Abstract: A non-iterative synthesis procedure for sub-harmonic stub (SHS) band-pass and band-stop filters is presented. The method ensures better agreement between the synthesized filter response and the original prototype function than was possible previously without iterative techniques. The procedure is illustrated for two L-band microstrip filters, with good agreement between modeled and measured responses.

Keywords: Microstrip filters, transmission line filters, filter synthesis

Introduction: With the advent of miniaturized satellite systems such as the CubeSat standard, multi-layer and compact system-in-package (SIP) microwave front-ends require filter topologies with minimum filter order and complexity, yet increasing selectivity. Finite transmission zeros in filters are used both for increasing pass-band selectivity [1] and creating wide stop-bands [2]. These zeros are typically realized with cross-coupled elements [3, 4], multiple mode resonators [5] or multiple transmission paths [6], all of which add to the filter's order, size and synthesis complexity.

A simple transmission line topology for realizing transmission zeros in both band-stop and band-pass filters was proposed [7, 8] whereby a conventional stub filter's shunt stubs were elongated to $2l_1$ and $4l_1$ to form sub-harmonic stubs (SHS), where l_1 is the conventional $\lambda_0/4$ length of a stub generated by Richard's transform [1] at a given stop-band or pass-band center frequency f_0 . In both cases, the authors relied on iteratively selected, rather than synthesized, values of impedance for the elongated stubs. This paper presents a synthesis procedure whereby an arbitrary frequency may be chosen to match the responses of the SHS filter and the original low-pass prototype response, thereby establishing a non-iterative synthesis method for this class of filters. This agreement may be used to preserve pass-band reflection, width or any other chosen parameter through the synthesis process. The process is demonstrated on both band-pass and band-stop filters.

Band-pass synthesis procedure: The filter synthesis starts as per the traditional method for synthesizing short- and open-circuited stub filters [1]. The parameters selected for the Chebyshev filter were $N = 3$ with 325 MHz transmission bandwidth around $f_0 = 1$ GHz and 0.5 dB pass-band transmission ripple. Using the transform

$$\Omega_c = \tan((\pi f_c)/(2f_0)) \quad (1)$$

the cut-off in the low-pass prototype is calculated as 3.832 Rad/s, leading (though low-pass to high-pass transformation and Richard's transforms) to the generalized circuit in Fig. 1 with block "A" representing a short circuit and "B" an open circuit termination. The response of the prototype function is marked as trace $-\Delta-$ in Fig. 2 with synthesized values of $Z_2 = 219.8 \Omega$, $Z_{1,3} = 12.65 \Omega$ and $f_{1,2,3} = 1$ GHz.

To realize the finite transmission zeros in the stop-band the short-circuited terminations of the shunt stubs (marked "A" in Fig. 1) are replaced by open-circuited

terminations, and the stubs Z_1 and Z_3 elongated. The impedance value of these SHS lines are calculated by considering the input impedance of the original shunt inductance L in the low-pass prototype

$$Z_{in(L)} = j\Omega_m L \quad (2)$$

at any given Richards' variable value Ω_m , which transforms *uniquely* to a given real frequency f_m . The input impedance of the open-circuit stub, at this frequency, is calculated as

$$Z_{in(Stub)} = -jZ_l \cot((\pi f_m)/(2f_z)) \quad (3)$$

where f_z is the frequency where the stub's length is equal to $\lambda_z/4$. A frequency f_m of exact correspondence may now be chosen, which will produce a unique impedance value Z_l for the stub by equating Eq. (2) and Eq. (3). The difference in choosing f_m in the band (0.9 GHz) or at the band edge (0.837 GHz) is shown in Fig. 2. It is observed that the in-band choice at 0.9 GHz achieves a better transmission band approximation to the original Chebyshev prototype function, and is chosen for manufacturing. The value of Z_2 remains unchanged from the initial synthesis, with $Z_2 = 79 \Omega$, $Z_3 = 27 \Omega$, $f_1 = 0.25$ GHz and $f_3 = 0.5$ GHz. To avoid having to manufacture an impractically high 219.8 Ω stub impedance or uniplanar short-circuited series stubs [9], the central open-circuit stub is divided into a cascade combination of two 109.9 Ω stubs (Fig. 3, with "A" representing open-circuited terminations). This split does, however, introduce a short but unavoidable section of transmission line Z_4 .

Band-stop synthesis procedure: Initial synthesis of the filter is identical to the method illustrated for band-pass filters, with the parameters of the Chebyshev prototype function chosen as $N = 3$, 0.5 dB pass-band transmission ripple and cut-off frequency

$f_c = 0.163$ GHz. The transformed Richards variable is calculated in Eq. (1) as 0.261 Rad/s, leading to the same generalized circuit shown in Fig. 1. In the case of the band-stop filter, “A” represents an open-circuited termination, whilst “B” represents a short circuit. The synthesized element values are $Z_2 = 219.8 \Omega$, $Z_{1,3} = 12.65 \Omega$ and $f_{1,2,3} = 1$ GHz. The circuit response is shown as the trace marked –Δ– in Fig. 4.

In the band-stop case, instead of calculating the appropriate impedance from a shunt inductor as in Eq. (2), the impedance of the two elongated stubs are calculated from the equivalent input impedance of a shunt capacitance C in the lumped element low-pass prototype

$$Z_{in(C)} = -j/(\Omega_m C) \quad (4)$$

at a given Richards’ variable value Ω_m , which transforms to a given real frequency f_m . This impedance is again equated to that of an an open-circuited shunt stub as in Eq. (3), yielding a unique impedance value for a given f_m . The result of choosing f_m at the band center (0.1 GHz) and band edge (0.163 GHz) are illustrated in Fig. 4. The former achieves a better approximation to the original Chebyshev prototype function in-band, and is selected for manufacturing. The value of Z_2 remains unchanged from the initial synthesis, with $Z_1 = 58 \Omega$, $Z_3 = 26 \Omega$, $f_1 = 0.25$ GHz and $f_3 = 0.5$ GHz. As with the band-pass filter, the 219.8 Ω stub is replaced by two 109.9 Ω stubs separated by a short section of transmission line, producing the same circuit model as in Fig. 3 but with “A” representing a short-circuited termination in the case of a band-stop filter.

Simulation and measurement results: Both filters were realized on two layers of 32mil Rogers RO4003C, as dimensioned in Fig. 5 and pictured in Fig. 6. For both the band-pass and band-stop filters, the light shaded trace is the filter’s top signal layer forming

the two series stubs Z_2 in Fig. 3. In the band-stop filter's case, the top strip is terminated with a via down to the lower signal layer, whilst in the band-pass filter these vias and via pads are omitted.

The band-pass filter is dimensioned (Fig. 5) as $w_0 = 1.5$, $w_1 = 1.86$, $w_2 = 0.86$, $w_3 = 6.29$, $l_1 = 169.01$, $l_2 = 91.86$, $l_3 = 82.7$ and $s = 9.44$. The previously noted Z_4 is created by the physical separation between the two stubs on the upper signal layer (dimensioned s in Fig. 5), and causes some discrepancy between the original circuit response and the simulated response. This effect is modeled by a line of length $\lambda/4$ at 0.8 GHz and impedance 109.93 Ω . The measured results (Fig. 7) were found to be in good agreement with the simulated response. The final filter features 0.6 dB mid-band insertion loss and -10 dB input match over a 280 MHz band centered at 1 GHz, with minimum out-of-band attenuation of -22 dB from DC to 4 GHz.

The band-stop filter is dimensioned (in mm, as shown in Fig. 5) as $d_{via} = 0.25$ mm, $w_0 = 1.5$, $w_1 = 1.12$, $w_2 = 0.4$, $w_3 = 4.15$, $l_1 = 164.25$, $l_2 = 90.4$, $l_3 = 80.6$, $d_{pad} = 0.5$ and $s = 2.63$. The responses in Fig. 7 show a pole created near f_0 due to the presence of the transmission line of length s on the upper signal layer. This is replicated in the circuit model (Fig. 8) with a transmission line of $Z_4 = 109.9 \Omega$ and $f_4 = 2.3$ GHz. Despite this unwanted circuit element, the filter exhibits -20 dB attenuation over the stop-band and below 0.1 dB pass-band ripples on either side of the stop-band, with the evenly spaced finite transmission zeros clearly visible.

Conclusion: A non-iterative synthesis process has been demonstrated for sub-harmonic stub band-stop and band-pass filters. The method has been demonstrated to produce filters with realizable impedance values that follow the input reflection response of the original prototype function better than was previously possible. The method suffers from some performance degradation due to unwanted additional

transmission lines in physical realization, but good agreement between circuit simulation and measured results are still obtained if these lines are taken into account in modeling.
