Abstract

Marine fish-processing plants often use seawater during their operations. Chlorination and UV are commonly used for disinfection of this water but may not be effective in preventing biofilm formation within the water distribution network. These biofilms negatively impact water quality and could lead to contamination of fish products. During a recent study, *Vibrio alginolyticus* strains were detected on processed hake. The presence of most *Vibrio* spp. on fish products is of consumer safety concern and needs to be minimised. Water treatment strategies effective for seawater disinfection but with minimal negative effect on fish quality are required. In this study the effectiveness of chlorine, ozone and hydrogen peroxide (H₂O₂) in the inhibition of mature biofilms or biofilm formation in natural seawater was investigated. Two *V. alginolyticus* strains (V590 and V595) isolated from hake fish as well as the type strains of *V. alginolyticus* LMG 4409 and *V. parahaemolyticus* LMG 2850 were used. Chlorine was ineffective as experiments showed that strains V590, V595 and *V. parahaemolyticus* LMG 2850 could form biofilms even in the presence of 4 mg/ℓ of chlorine. When ozone was used, biofilm initiation and formation were completely inhibited for only 2 strains of *V. alginolyticus*, i.e. LMG 4409 and V590, at 1.6 mg/ℓ or 0.8 mg/ℓ ozone, respectively. Hydrogen peroxide performed the best of all the disinfectants evaluated in this study. Inhibition of biofilm formation was observed for all strains at 0.05% H₂O₂. The mature biofilms were more resistant to H₂O₂ but were all eliminated at 0.2% concentrations. This study indicated that H₂O₂ is the most effective biocide to prevent biofilm formation in seawater distribution networks and could potentially be used as an alternative or supplementary disinfectant of seawater in marine fish-processing plants.

Keywords: *V. alginolyticus*, *V. parahaemolyticus*, biofilms, H₂O₂, disinfection, seawater

Introduction

The use of seawater instead of freshwater during marine fish processing is an economical alternative, especially in arid countries such as Namibia which are often faced with severe freshwater shortages. The water is typically used for activities such as cooling of the product or washing of surfaces and apparatus in the plant. Seawater may, however, contain human pathogenic bacteria including *Vibrio* species such as *V. parahaemolyticus*, *V. cholerae*, *V. vulnificus* and *V. alginolyticus* (Thompson et al., 2004; Wekell et al., 1994). The water, therefore, requires treatment and disinfection before being used for the processing of fresh fish. Currently chlorination and UV treatment are mostly commonly used to disinfect the water.

A recent study at a fish-processing plant showed that the quality of hake deteriorated along the processing line (author’s own observation). *Vibrio* species were isolated at the intermediate stages of processing. None of these species were isolated from the fish which had just been delivered to the factory for processing. From the study it was clear that *Vibrio alginolyticus* strains were introduced by the treated seawater used during processing. Indications were that the major source of these bacteria was not the processing of the fish poses a potential health hazard to consumers and should be minimised and controlled. Chlorine, or chloramines, are typically used to control bacterial biofilms in freshwater distribution systems (DeQueiroz and Day, 2007; Momba et al., 2002), but many studies have described the ineffectiveness of chlorine in controlling biofilm formation (Chu et al., 2003; Momba et al., 1998). There is, however, little information in the literature on alternative disinfectant strategies to control biofilm formation in seawater systems. The type and level of disinfectant to be used are, however, restricted, as high concentrations of disinfectants have been shown to cause discoloration of the fish due to oxidation of the myoglobin (Kim et al., 2000).

The aim of this study was to evaluate 3 different oxidising disinfectants to control biofilm formation by selected *Vibrio* isolates in seawater distribution systems. For this purpose chlorine, ozone and hydrogen peroxide were tested at a range of concentrations. Improvement in the treatment, disinfection and microbiological quality of the seawater used for fish processing would help to ensure the safety of the final product and protect consumers.

Materials and methods

Sampling and analysis of treated seawater

Samples of seawater used in a fish-processing facility in Walvis Bay, Namibia, were collected to evaluate the current treatment...
Biofilm formation in artificial seawater

The ability of the selected bacteria to form biofilms in seawater was evaluated using a Pedersen’s device (Pedersen, 1982). The device contained 20 clean microscope glass slides (7.6 x 2.6 cm) and was connected by means of silicone tubing via a peristaltic pump to a reservoir containing artificial seawater. Sterile artificial seawater (ASW) instead of natural seawater was used for these experiments due to logistical constraints of transporting and storing large volumes of water. The ASW was supplemented with bacteriological peptone (Biolab) and nutrient broth (NB) (Biolab) at 1 g/l each. The effluent was collected, disinfected and discarded. The system was disinfected by perfusing the systems with bacteriological peptone (Biolab) and nutrient broth (NB) at 1 g/l each. After inoculation with 1 ml of the test culture suspension, the systems were allowed to run for 30 min and washed twice with 0.85% (w/v) NaCl. The pellet was re-suspended in 15 ml 0.85% NaCl to obtain an inoculum containing ±10^7 CFU/ml.

Biofilm formation in artificial seawater

The type strains of *Vibrio alginolyticus* (LMG 4409) and *V. para-haemolyticus* (LMG 2850) were also included for comparative purposes. Both these strains were isolated from the processing plant. Isolate V590 was isolated from hake after filleting by the Baader machine, and V595 was isolated from the finished product. These strains were identified using the API 20E (Biomérieux) test and amplification of the collagenase gene according to the method of di Pinto et al. (2006). The type strains of *V. alginolyticus* and *V. para-haemolyticus* were also included for comparative purposes. Both these strains were initially isolated from food-processing incidents related to seafood. Strains were cultured individually on seawater agar (SWA) by incubation overnight at 37°C. This culture was then used to inoculate 250 ml sterile nutrient broth (NB) containing 3% NaCl and incubated unshaken at 37°C for 24 h. The cell suspension (75 ml) was harvested by centrifugation at 4,000 r/min for 30 min and washed twice with 0.85% (w/v) NaCl. The pellet was re-suspended in 15 ml 0.85% NaCl to obtain an inoculum containing ±10^7 CFU/ml.

**Biofilm formation in artificial seawater**

The ability of the selected bacteria to form biofilms in seawater was evaluated using a Pedersen’s device (Pedersen, 1982). The device contained 20 clean microscope glass slides (7.6 x 2.6 cm) and was connected by means of silicone tubing via a peristaltic pump to a reservoir containing artificial seawater. Sterile artificial seawater (ASW) instead of natural seawater was used for these experiments due to logistical constraints of transporting and storing large volumes of water. The ASW was supplemented with bacteriological peptone (Biolab) and nutrient broth (NB) (Biolab) at 1 g/l each. The effluent was collected, disinfected and discarded. The system was disinfected by perfusing the systems for 24 h with tap water containing 0.4 M NaCl, 0.1 M MgSO_4·7H_2O, 0.02 M KC1 and 0.02 M CaCl_2·2 H_2O had been dissolved (Farmer III and Hickman-Brenner, 1991).

**Bacterial cultures and inoculum**

Four bacterial isolates were included in this study. Two of the isolates were *Vibrio alginolyticus* strains previously isolated from the processing plant. Isolate V590 was isolated from hake after filleting by the Baader machine, and V595 was isolated from the finished product. These strains were identified using the API 20E (Biomérieux) test and amplification of the collagenase gene according to the method of di Pinto et al. (2006). The type strains of *V. alginolyticus* (LMG 4409) and *V. para-haemolyticus* (LMG 2850) were also included for comparative purposes. Both these strains were isolated from food-processing incidents related to seafood. Strains were cultured individually on seawater agar (SWA) by incubation overnight at 37°C. This culture was then used to inoculate 250 ml sterile nutrient broth (NB) containing 3% NaCl and incubated unshaken at 37°C for 24 h. The cell suspension (75 ml) was harvested by centrifugation at 4,000 r/min for 30 min and washed twice with 0.85% (w/v) NaCl. The pellet was re-suspended in 15 ml 0.85% NaCl to obtain an inoculum containing ±10^7 CFU/ml.
Results

Microbial quality of treated seawater

The aerobic heterotrophic, psychrotrophic and *Vibrio* culturable counts were determined for the treated seawater used in the Namibian fish-processing plant and are presented in Table 1. The heterotrophic and psychrotrophic counts for the untreated seawater (S1) were $2.0 \times 10^2$ (cfu/mℓ) and $5.6 \times 10^3$ (cfu/mℓ), respectively, and only 10 cfu/mℓ of presumptive *Vibrio* colonies was detected. Similar heterotrophic and psychrotrophic results were observed after dissolved air flotation (DAF) and chlorination. At this point of the treatment no *Vibrio* spp. were detected. The water leaving the plant after UV disinfection had very low numbers of both heterotrophic ($60$ cfu/mℓ) and psychrotrophic bacteria ($35$ cfu/mℓ). No *Vibrio* spp. were detected in this sample. Inside the processing plant the value of both the heterotrophic bacteria and the psychrotrophic bacteria had risen sharply to the similar levels detected in the raw water. Growth of *Vibrio* spp. above the detection limit of 250 cfu/mℓ was also observed on the TSBC plates after 72 h of incubation (Table 1).

Ability of *Vibrio* isolates to form biofilms in seawater

All *Vibrio* strains included in this study were able to form biofilms on glass slides in artificial seawater (ASW) supplemented with bacteriological peptone and nutrient broth (Fig. 1). The average bacterial densities in the biofilms peaked at between $10^7$ and $10^9$ cfu/cm$^2$ after 72 h, changing only slightly over the next 24 h.

Effect of disinfectant on biofilm formation

The development of biofilms in the presence of different predetermined concentrations of disinfectant was measured. After 72 h of exposure to the chlorine concentrations biofilm formation was observed for almost all of the strains (Fig. 2a). At the lower chlorine concentrations (1.5 mg/l and below) there was no significant reduction in bacterial densities; however, there was a significant difference in the mean bacterial counts between the control without chlorine and the highest chlorine concentration (4 mg/l) used (LSD=1.24) (Fig. 2a). The bacterial densities of strains V590, V595 and LMG 2850 dropped to log 3.73, 2.33 and 2.88, respectively, while *V. alginolyticus* type strain (LMG 4409) did not form biofilm at a chlorine concentration of 4 mg/l.

Biofilm formation varied substantially between the different *Vibrio* strains (Fig. 2b) at the different concentrations of ozone used. There was a significant interaction between *Vibrio* strains and the disinfectant ($p<0.001$). For the *V. alginolyticus* isolates, strains V590 and LMG 4409, biofilm formation was

completely inhibited at 0.8 mg/l and 1.6 mg/l, respectively. Biofilm formation was, however, still observed for *V. parahaemolyticus* (LMG 2850) and one of the *V. alginolyticus* fish isolates (V595) after 72 h of exposure to 2.0 mg/l ozone (Fig. 2b). Statistically, the overall response of V595 was similar to that of *V. parahaemolyticus* LMG 2850. Their responses were, however, significantly different from that of *V. alginolyticus* LMG 4409 and V590. No formation of biofilms could be detected after 24 h at any of the H$_2$O$_2$ concentrations tested.

**Effect of disinfectants on mature biofilms**

Chlorine had a limited impact on the bacterial levels of all 3 *V. alginolyticus* biofilms after 1 h of exposure (Fig. 3a) when compared to the control value. *Vibrio parahaemolyticus* LMG 2850 was more sensitive to chlorine, with a significant reduction in bacterial numbers. After 1h of exposure to 4 mg/l, the bacterial density dropped from 8.03 x $10^7$ to 9.43 x $10^6$ cfu/cm$^2$ (Fig. 3a). At 4 mg/l, the reactions of the type strains, *V. parahaemolyticus* LMG 2850 and *V. alginolyticus* LMG 4409, to chlorine were not significantly different, but they differed from those of the 2 fish isolates that were more resistant to chlorine. The ozone treatments resulted in a typical 1 log reduction in the bacterial levels, independent of the ozone concentration used (Fig. 3b) and these reductions were not statistically significant ($p=0.166$).

There was a significant reduction in bacterial counts of the mature biofilms of all the *Vibrio* isolates (Fig. 3c) as the H$_2$O$_2$ concentration increased ($p<0.001$). Of all the strains tested, *V. parahaemolyticus* strain LMG 2850 was the most sensitive and the mature biofilm could be inhibited after 1 h of exposure to 0.08% H$_2$O$_2$. The *V. alginolyticus* type strain (LMG 4409) biofilms were inhibited at 0.1% H$_2$O$_2$. The 2 *V. alginolyticus* strains isolated from the facility (V590 and V595) were more difficult to remove and were only inhibited after 1 h exposure to 0.2% H$_2$O$_2$ (Fig. 4c).

**Discussion**

For many marine fish-processing facilities the use of treated seawater during operations is a viable economic alternative to the use of freshwater. The microbial quality of the water should be well managed as it may have a negative impact on the quality and safety of the final product. During an investigation into the deterioration of the microbial quality of hake during processing, *V. alginolyticus* strains most likely introduced by the treated seawater used during processing were isolated (author’s own observation). Although certain strains of *V. alginolyticus* have been shown to be pathogenic, it is their close relationship to *V. parahaemolyticus*, a pathogen widely associated with food-borne infections and outbreaks linked to seafood (Thompson et al., 2004) that is of even greater concern. The ability of these *V. alginolyticus* strains to survive and grow in treated seawater and the subsequent contamination of the hake may, therefore, be indicative of a similar behaviour of *V. parahaemolyticus*, should this pathogen be present. Control of this route of contamination is, therefore, of great importance for the efforts to minimise potential health hazards to consumers.

The first focus of the study was to survey the quality of the seawater used at the facility and to investigate whether it could serve as a source of contamination. Results showed that chlorination combined with UV irradiation drastically reduced both the mesophilic and psychrotrophic bacteria in seawater. Although the quality of the water directly after these treatments was very good, it deteriorated during distribution and some *Vibrio* spp. could be detected. It was clear from these data that the residual chlorine was ineffective in inhibiting biofilm formation in the distribution network. This was not unexpected as biofilm formation is common in water distribution networks (September et al., 2007) and detachment of the biomass can lead to deterioration of the microbial quality of the water.

Under a defined set of conditions of temperature, pH and a limited supply of nutrients, the 4 *Vibrio* isolates selected for this study were able to form monoculture biofilms on glass slides in the Pedersen device. This was not unexpected as biofilm formation by *V. alginolyticus* has previously been demonstrated by Kogure et al. (1998). The biofilm formation...
of the fish isolates (V595 and V590) was similar to that of the *V. parahaemolyticus* (LMG 2850) and *V. alginolyticus* (LMG 4409) type strains. These results support the hypothesis that the *Vibrio* species detected on hake fish could have originated from bacteria released from biofilms that formed in the water distribution network after the initial treatment. It also showed that there was little difference in the overall behaviour of the *V. alginolyticus* strains isolated from the facility and the *V. parahaemolyticus* type strain. All isolates were quite similar in terms of their ability to form biofilms and their resistance to specific disinfectants.

Chlorine is not very effective against biofilms formed by either atypical *V. alginolyticus* isolates or the *V. parahaemolyticus* type strain LMG 2850 in seawater. The effectiveness of chlorine against microorganisms in freshwater depends on a number of factors including the residual concentration, contact time, temperature, pH, and aggregation (Obi et al., 2008). Not much attention has, however, been given to the possible additional inhibitors of chlorine that might exist in water with high salt concentrations such as seawater. From the historical data kept at the factory it is clear that a residual chlorine concentration of 0.2 mg/ℓ was constantly maintained in the system. These conditions might have selected for strains with an ability to tolerate high chlorine concentrations as was previously demonstrated by Ridgeway and Olson (1982). From the responses of the *V. parahaemolyticus* type strain it can be deduced that this bacterium will behave similarly in the seawater distribution system and may, therefore, contaminate the final product whenever present.

Failure of chlorine to inhibit biofilm formation and mature biofilms was not due to the effect of pH. The pH of the NSW was 7.4, a level at which both HOCl and OCl⁻ exist in various proportions (LeChevallier et al., 2004). In this study the CT (concentration x exposure time) value for the highest concentration used (4 mg/ℓ) was 288 after 72 h exposure, a value that was much higher than the 15 to 150 CT values recommended for drinking water (Debore and Von Gunten, 2008). The use of chlorine at concentrations higher than 4 mg/ℓ was not considered, due to the potential effect that higher chlorine levels might have on costs, acceptability of the final product, corrosion in the plant and the potential to generate possible carcinogens (Gopal et al., 2007; Wang et al., 2007).

The ability of ozone to inhibit biofilm formation varied between the strains tested. Again *V. alginolyticus* V595 was the most resistant to ozone, and biofilm formation was not inhibited at 2 mg/ℓ ozone. Although biofilm formation could be inhibited for *V. alginolyticus* V590 at an ozone concentration of 0.8 mg/ℓ, none of the mature biofilms was inhibited at the highest concentrations of ozone used (2 mg/ℓ) in this study. Higher ozone concentrations to remove mature biofilms are, however, not recommended. Reports have shown that at high concentrations ozone reacts with organic matter in water, generating nutrients that could stimulate bacterial attachment to surfaces and formation of biofilms (Clark et al., 1994). Ozone is also not stable for long periods and may not provide the level of residual disinfectant required to inhibit existing biofilms (Khadre et al., 2001; Guzel-Seydim et al., 2004).

Hydrogen peroxide (H₂O₂) was very effective in inhibiting biofilm formation at a concentration of 0.05% (500 mg/ℓ) H₂O₂. Mature biofilms of all 4 strains tested could be killed at concentrations between 0.08% and 0.2% H₂O₂. This suggested that H₂O₂ at higher concentrations could be used to remove existing mature biofilms from seawater distribution systems during shock dose treatments. During this study H₂O₂ was more effective in killing bacteria than during a study done by Kim et al. (2000) on channel catfish carried out in freshwater. The discrepancy found in H₂O₂ action between seawater and freshwater could be ascribed to different disinfection environments implying that mineral ions present in seawater are essential in maximising the action of H₂O₂ against bacteria. Pedahzur et al., (1995) found such a synergistic effect between silver ions and H₂O₂ when inactivating *E. coli* in phosphate buffer.

Part of the success of H₂O₂ was that it could be used at a higher concentration than the other 2 disinfectants without negatively affecting the product quality. Kim et al., (2000) investigated the effectiveness of 0.7% (7 000 mg/ℓ) H₂O₂ on reducing bacterial counts on catfish fillets and found no significant differences between controls and H₂O₂ treated fillets with regard to appearance, colour, and odour scores. The levels of H₂O₂ used by Kim et al. (2000) were 10 times higher than the concentrations used in this study.

**Conclusion**

This study has shown that although seawater could be an alternative source of water for marine fish-processing plants the treatment and the quality of the water needs to be carefully managed. The conditions in this seawater distribution network have selected for *V. alginolyticus* strains that can form biofilms in the presence of a residual chlorine concentration of 0.2 mg/ℓ. Once present in the system these bacteria may be released from the biofilm and would contaminate the fish during processing. The presence of *V. alginolyticus* on its own is not of great health concern as it is rarely associated with cases of diarrhea or gastroenteritis. *V. alginolyticus* is, however, closely related to the common food-borne pathogen, *V. parahaemolyticus*, and may be predicative of the growth, behaviour and survival of this seafood pathogen in the water system. The current study has confirmed that this is the case as there was little difference between the behaviour of strains representing these 2 species in the experiments conducted. This finding also emphasised the need for control of biofilm growth in distribution systems even though it may not currently pose a significant health threat.

Evaluation of 3 oxidising disinfectants showed that chlorine and ozone are ineffective in preventing biofilm formation and in removing mature biofilms formed by *Vibrio* species in seawater at their permissible concentrations. The only disinfectant that showed some promise was H₂O₂. Bench-scale experiments indicated that it would be possible to control biofilm formation at a concentration of 0.05% (500 mg/ℓ) H₂O₂ and that existing biofilms could be removed by shock doses of 0.2%. This still needs to be investigated with larger-scale experiments run over a longer period of time. Results published by Kim et al., (2000) strongly support the notion that the proposed levels of H₂O₂ would not have any negative effect on the quality of the processed hake, but further studies would be required to confirm these conclusions.
