Promotor: Prof F.E. Steffens

## DECLARATION

I, Nicolene Magrietha Thiebaut declare that the dissertation, which I hereby
submit for the degree MSc at the University of Pretoria, is my own work and has
not previously been submitted by me for a degree at this or any other tertiary institution.

Signature:

Date: $\qquad$

## ACKNOWLEDGEMENTS:

I wish to record my sincere thanks and appreciation to the following persons and institutions for their contributions to this dissertation:

The Agriculture Research Council (ARC) for allowing me to further my studies and for offering me a bursary.

Prof. F. E Steffens from the Department of Statistics of the University of Pretoria, prof. Crowther and the other lecturers for their assistance and guidance.

My friend Hartmut, my daughter Nicole, family and other friends for their patience and support.

All the contributions are highly appreciated.

## ABSTRACT:

In practice, when one has many candidate variables as explanatory variables in multiple regression, there is always the possibility that variables that are important determinants of the response variable might be omitted from the model, while unimportant variables might be included. Both types of errors are important, and in this dissertation it is attempted to quantify the probabilities of these errors.

A simulation study is reported in this dissertation. Different numbers of variables, i.e. $\mathrm{p}=$ 4 to 20 are assumed, and different sample sizes, i.e. $n=0.5 p, p, 2 p, 4 p$. For each $p$ the underlying model assumes that roughly half of the independent variables are actually correlated with the dependant variable and the other half not. The noise is $\varepsilon \sim N\left(0, \sigma^{2}\right)$, where $\sigma^{2}$, is set fixed. The data was simulated 10000 times for each combination of $n$ and p using known underlying models and $\varepsilon$ randomly selected from of a normal distribution.

For this investigation the full model and forward selection regression are compared. The mean squared error of the estimated coefficient $\hat{\beta}(\mathrm{p})$ is determined from the true $\beta$ of each $n$ and $p$ set. A full discussion, as well as graphs, is presented.

## Chapter 1

## INTRODUCTION

When selecting variables in regression, certain procedures are followed. If one wishes to establish a linear regression equation for a particular response $Y$ (in terms of the predictor variables $X_{1}, X_{2}, X_{3} \ldots X_{p}$ and furthermore if $Z_{1}, Z_{2}, Z_{3} \ldots Z_{k}$, were all functions of one or more of the x's as well as the whole set of functions, such as logarithms, inverses etc.), then the following two generally opposed criteria shall be considered:

1) To make the equation useful for prediction purposes, as many predictors as possible should be included - this normally results in a small bias so that reliable fitted values can be determined.
2) To keep the variance of the predictions as small as possible (for a certain $p$, i.e. the number of variables, and n, i.e. the number of observations) to minimize costs involved in obtaining information on large numbers of predictors and the subsequent monitoring of them, the number of predictors must be as small as possible to be cost effective and easily interpretable.

The different methods for "Selecting the best regression equation" are illustrated, followed by an overview of the full regression model and forward selection. A description of the program, i.e. programmed in SAS IML, and information about the parameters chosen for the study are also given. The final part of this dissertation comprises a summary and conclusion of the study.

## Chapter 2

## SELECTING THE "BEST" REGRESSION EQUATION.

The practical compromise between the extremes described in 1) and 2) above is normally regarded as the best regression equation. There are no definite procedures for this selection process. Although many procedures have been suggested, the methods commonly used in choosing the best regression model are the following ${ }^{1}$ :
a) The full model (includes all predictors)
b) The best subset regression using: $R^{2}$ (adjusted) and $C_{p}$.
c) Forward regression (there are variations on this method)
d) Stepwise regression
e) Backward elimination
f) Variations on previous methods.

These methods should be regarded as exploratory analysis (not providing a definite proof that the selected model is a true reflection of the real life situation).

When using the above methods there can be problems such as:

[^0]- Possible multicollinearity among the explanatory variables.
- Too few observations
- Several possible models to choose from.

In the following section an overview of the above-mentioned methods, as well as an example is given. The full regression model is used for comparison in this study.

## a) The full multiple linear regression model

All the terms are included in the model. In matrix notation, the model is given by:

$$
\boldsymbol{y}=\boldsymbol{X} \boldsymbol{\beta}+\boldsymbol{\varepsilon} \quad \text { where: }
$$

$\boldsymbol{y}=\left[\begin{array}{c}y_{1} \\ y_{2} \\ \vdots \\ y_{n}\end{array}\right], \quad \boldsymbol{X}=\left[\begin{array}{ccc}1 & x_{11} \ldots & x_{1 p} \\ 1 & x_{21} \cdots & x_{2 p} \\ \vdots & \vdots & \vdots \\ 1 & x_{n 1} \cdots & x_{n p}\end{array}\right], \quad \boldsymbol{\beta}=\left[\begin{array}{c}\beta_{0} \\ \beta_{1} \\ \vdots \\ \beta_{p}\end{array}\right], \quad \boldsymbol{\varepsilon}=\left[\begin{array}{c}\varepsilon_{1} \\ \varepsilon_{2} \\ \vdots \\ \varepsilon_{n}\end{array}\right]$
$\mathbf{y}$ is an $\mathrm{n} \times 1$ vector of observations, $\mathbf{X}$ is an $\mathrm{nx}(\mathrm{p}+1)$ matrix, $\boldsymbol{\beta}$ is a $(\mathrm{p}+1) \times 1$ vector of the regression coefficients and $\varepsilon$ is an $n \times 1$ vector of random errors.

The aim is to find the vector of the least-square estimators $\widehat{\boldsymbol{\beta}}$, that minimizes:
$S(\boldsymbol{\beta})=\sum_{i=1}^{n} \varepsilon_{i}^{2}=\boldsymbol{\varepsilon} ` \boldsymbol{\varepsilon}=(\mathbf{y}-\boldsymbol{X} \boldsymbol{\beta})^{`}(\mathbf{y}-\boldsymbol{X} \boldsymbol{\beta})$

The least-square estimators must satisfy
$\left.\frac{\partial S}{\partial \beta}\right|_{\widehat{\beta}}=0 \quad$ which simplify to
$X^{\prime} X \widehat{\beta}=X \quad y$
which are the least square normal equations.
The least-square estimator of $\boldsymbol{\beta}$ is then:

$$
\widehat{\beta}=\left(X^{`} X\right)^{-1} X^{`} y
$$

provided that the inverse matrix $\left(\boldsymbol{X}^{\mathbf{}} \boldsymbol{X}\right)^{-\mathbf{1}}$ exists. For this reason the full linear model cannot be calculated where $\mathrm{n}<\mathrm{p}$.
t-test and F-test have been used in this study and are the following:
Test: $\beta_{j}=0 \rightarrow t=\frac{\left(\widehat{\boldsymbol{\beta}}_{j}\right)}{\sqrt{\operatorname{var}\left(\widehat{\beta}_{j}\right)}} \quad(0<\mathrm{j}<\mathrm{p})$ and where $\mathrm{t} \sim t(n-k-1)$
$\rightarrow \quad \mathrm{F}=\frac{\left(\widehat{\boldsymbol{\beta}}_{j}\right)^{2}}{\operatorname{var}\left(\widehat{\beta}_{j}\right)}=\mathrm{t}^{2} \quad$ where $\mathrm{F} \sim F(1, n-k-1)$
where $\operatorname{var}(\widehat{\boldsymbol{\beta}})=\boldsymbol{\sigma}^{\mathbf{2}}\left(\boldsymbol{X}^{\top} \boldsymbol{X}\right)^{\mathbf{- 1}}, \quad$ with $\sigma^{2}=\operatorname{var}\left(\mathrm{y}_{\mathrm{i}}\right)$

$$
\widehat{\operatorname{var}}(\widehat{\boldsymbol{\beta}})=s^{2}\left(\boldsymbol{X}^{\prime} \boldsymbol{X}\right)^{-1} \text { and }\left(\boldsymbol{s}^{2}\left(\boldsymbol{X}^{\prime} \boldsymbol{X}\right)^{-1}\right)_{j+1, j+1}=\widehat{\operatorname{var}}\left(\widehat{\boldsymbol{\beta}}_{j}\right)
$$

with $s^{2}$ the mean-square about regression (MSE)

## Example:

For illustration purposes $x_{1}, x_{2}, x_{3}$ and $x_{4}$ are generated each from a normal distribution where $\mathrm{x}_{\mathrm{i}} \sim N(0,1) \mathrm{n}=30$ is used, and $\mathrm{y}_{\mathrm{i}} \sim N(0,1)$.

The data generated was the following:

| y | x 0 | x 1 | x 2 | x 3 | x 4 |
| :---: | :--- | :--- | :--- | :--- | :--- |

|  |  |  |  |  |  |  |
|  |  |  |  |  |  |  |

*. Correlation is significant at the 0.05 level (2-tailed).
The $R^{2}$ value is: 0.42 which gives an indication of a linear trend.

| Model | R | R Square | Adjusted R Square | Std. Error of the Estimate |
| :--- | ---: | ---: | ---: | ---: |
| 1 | $.647^{\mathrm{a}}$ | .418 | .325 | .64681 |

The F - probability of the ANOVA is: 0.007 , which indicates statistically a significant model.

| ANOVA ${ }^{\text {b }}$ |  |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Model |  | Sum of Squares | df | Mean Square | F | Sig. |
| 1 | Regression | 7.519 | 4 | 1.880 | 4.493 | . $007^{\text {a }}$ |
|  | Residual | 10.459 | 25 | . 418 |  |  |
|  | Total | 17.978 | 29 |  |  |  |

a. Predictors: (Constant), x4, x2, x1, x3
b. Dependent Variable: y

The coefficients marked are statistically significant at the $5 \%$ level.

Coefficients ${ }^{\text {a }}$

| Model |  | Unstandardized Coefficients |  | Standardized <br> Coefficients | t | Sig. |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | B | Std. Error | Beta |  |  |
| 1 | (Constant) | *. 529 | . 121 | . 265 | 4.387 | . 000 |
|  | x1 | . 180 | . 105 |  | 1.717 | . 098 |
|  | x2 | *. 339 | . 151 | . 352 | 2.238 | . 034 |
|  | x3 | -. 120 | . 143 | -. 133 | -. 842 | . 408 |
|  | x4 | *. 306 | . 124 | . 384 | 2.464 | . 021 |

a. Dependent Variable: y

The equation of the full model is then:
$y=0.529+0.180 x_{1}+0.339 x_{2}-0.120 x_{3}+0.306 x_{4}$.
The full model thus includes non-significant terms.
b) The best subset regression using: $\mathbf{R}^{\mathbf{2}}$ (adjusted) and $\mathrm{C}_{\mathrm{p}}$

- This is a complicated regression technique. It requires the fitting of every possible regression equation that involves $Z_{0}$ plus any number of variables $Z_{1} \ldots . . Z_{r}$, where $Z_{0}$ is the intercept term. In this example the transformation and other combinations of the $Z$ terms will not be fitted.
- The three criteria most often used are the following:
- The value of $R^{2}$ achieved by the least squares fit.
- The value of the $s^{2}$, the residual mean square.
- The $\mathrm{C}_{\mathrm{p}}$ statistic.

These criteria are related to each other.
All three the above criteria are used to obtain the best regression equation. The fitting of regression equations that involve more predictor variables than are necessary to obtain a satisfactory fit to data is called over-fitting. With these criteria over-fitting can be prevented.
c) Forward selection

- Firstly choose the variable most highly correlated with $y$;
- Fit the regression and calculate the residuals;
- Choose the variable best correlated with the residuals (if significant);
- Repeat the above sequence until all the variables have been selected, or until there are no more significant correlations with the residuals.

The following flowchart illustrates this selection.

## Example continued:

The $R^{2}=0.332$ of $y$ with the variables $x_{2}$ and $x_{4}$ in the model indicates that there is some linear trend.

Model Summary ${ }^{\text {c }}$

| Model | R | R Square | Adjusted R Square | Std. Error of the Estimate | Change Statistics |  |  |  |  |

|  | Total | 17.978 | 29 |  |  |  |
| 2 | Regression | 5.969 | 2 | 2.985 | 6.711 | $.004^{\mathrm{b}}$ |
|  | Residual | 12.008 | 27 | .445 |  |  |
|  | Total | 17.978 | 29 |  |  |  |

a. Predictors: (Constant), x4
b. Predictors: (Constant), $x 4, \times 2$
c. Dependent Variable: y

## Coefficients ${ }^{\text {a }}$

| Model |  | Unstandardized Coefficients |  | Standardized <br> Coefficients <br> Beta | t | Sig. |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | B | Std. Error |  |  |  |
| 1 | (Constant) | . 512 | . 131 |  | 3.903 | . 001 |
|  | x4 | . 366 | . 134 | . 459 | 2.735 | . 011 |
| 2 | (Constant) | . 506 | . 123 |  | 4.119 | . 000 |
|  | x4 | . 346 | . 126 | . 433 | 2.748 | . 011 |
|  | x2 | . 336 | . 152 | . 349 | 2.214 | . 035 |

ANOVA ${ }^{\text {c }}$

| Model |  | Sum of Squares | df | Mean Square | F | Sig. |
| :--- | :--- | ---: | ---: | ---: | ---: | ---: |
| 1 | Regression | 3.790 | 1 | 3.790 | 7.480 | $.011^{\mathrm{a}}$ |
|  | Residual | 14.188 | 28 | .507 |  |  |
|  | Total | 17.978 | 29 |  |  |  |
| 2 | Regression | 5.969 | 2 | 2.985 | 6.711 | $.004^{\mathrm{b}}$ |
|  | Residual | 12.008 | 27 | .445 |  |  |
|  | Total | 17.978 | 29 |  |  |  |

a. Predictors: (Constant), x4
b. Predictors: (Constant), $x 4, x 2$
a. Dependent Variable: y

The final model with the forward regression is then:
$y=0.506+0.336 x_{2}+0.346 x_{4}$
(The normality plot and the y-fitted versus residuals plot seem to be more acceptable than those of the full model.)

## d) Stepwise regression.

Stepwise regression is an improved version of forward regression, which permits reexamination at every step of the variables incorporated in the model in previous steps. A variable that entered at any early stage may become superfluous at a later stage, because of its relationship with the other variables in the model at that particular moment.

The following steps are taken:

- The regression starts in the same manner as in forward selection;
- A variable can be added or removed at any stage - it is removed when the regression coefficient is no longer "significant";
- The criterion for removing a variable must be stricter than for entering it.

The following flowchart illustrates this selection:

[^1]
## Example continued:

Stepwise regression gives the same results as the forward regression model. X4 and then x 1 are included in the model and no variables are removed.

The final model with stepwise regression is: $\quad y=0.506+0.336 . x 2+0.346 . x 4$.

## e) Backward elimination

- Start with the full model, i.e. all the predictor variables must be within the model this can only be done when $n>p$, otherwise $X^{\prime} X$ will be singular;
- Eliminate the least significant variable and recalculate the regression;
- All the remaining regression coefficients must be significant when the selection stops.

The following flowchart illustrates this selection

## Example (continued):

There is no significant change in the $R^{2}$ value when $x_{3}$ is taken out of the model. The final $R^{2}$ value is 0.402 .

Model Summary ${ }^{\text {c }}$

| Model | R | R Square | Adjusted R Square | Std. Error of the Estimate | Change Statistics |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  |  |  |  | R Square <br> Change | F Change | df1 | df2 | Sig. F <br> Change |
| 1 | . $647^{\text {a }}$ | . 418 | . 325 | . 64681 | . 418 | 4.493 | 4 | 25 | . 007 |
| 2 | . $634{ }^{\text {b }}$ | . 402 | . 333 | . 64317 | -. 016 | . 709 | 1 | 25 | . 408 |

a. Predictors: (Constant), $x 4, x 2, x 1, x 3 \quad$ b. Predictors: (Constant), $x 4, x 2, x 1 \quad$ c. Dependent Variable: $y$

The ANOVA with $\mathrm{x} 1, \mathrm{x} 2$ and x 4 is statistically significant. (Fprob=0.004)

|  | x 1 | . 180 | . 105 | . 265 | 1.717 | . 098 |
|  | x2 | . 339 | . 151 | . 352 | 2.238 | . 034 |
|  | x3 | -. 120 | . 143 | -. 133 | -. 842 | . 408 |
|  | x4 | . 306 | . 124 | . 384 | 2.464 | . 021 |
| 2 | (Constant) | . 514 | . 119 |  | 4.335 | . 000 |
|  | x1 | . 181 | . 104 | . 267 | 1.740 | . 094 |
|  | x2 | . 365 | . 147 | . 379 | 2.477 | . 020 |
|  | x4 | . 323 | . 122 | . 405 | 2.650 | . 014 |

a. Dependent Variable: y

The removal of variables was done if the significant value were $>0.1$. That is why x 1 is not removed out of the model.

The final model is then:
$\mathrm{y}=0.514+0.181 \mathrm{x}_{1}+0.365 \mathrm{x}_{2}+0.323 \mathrm{x}_{4}$
f) Variations on previous methods.

Variations of the methods above can also be used.

Comment on example: This is not a very good model. The $R^{2}$ is around 0.40 , which is not good for fitting a linear model. This example was only used for illustrating purposes to show the different methods.

## Chapter 3

## LITERATURE STUDY

There is no unique method in finding the "best regression equation". In this chapter a few discussions will be made in finding the best probable model, taking the previous mentioned multiple regression analysis methods into account, and by focussing on forward selection and some other discussions from the literature.

It is usually assumed that the correct functional specification of the regressors is known (e.g. $1 / x_{1}, \ln x_{2}$ ) and that no outliers or influential observations are present. If outlier observations were present, it must be removed and the variable selection process must be repeated.

When doing the selection of variables in regression analysis, some important aspects to consider will be discussed. Variable selection procedures should be used by the analyst as methods to explore the structure of the data. There is usually not a single best equation but rather several good ones.

In this study the focus is on the accuracy of a model using forward selection in multiple, linear regression.

A few important concepts used in selecting the best possible linear model, as well as concepts that influence the error in a regression model are discussed.

## - ASSUMPTIONS ABOUT THE ERROR TERM ARE THE FOLLOWING:

(The assumptions will influence the accuracy of the regression analysis).

1) The residuals must have a zero mean, i.e. $\mathrm{E}\left(\varepsilon_{i}\right)=0$.
2) Homoscedasticity, i.e. $\operatorname{Var}\left(\varepsilon_{i}\right)=\sigma^{2}$ for all i's (constant variance).
3) Normality: for statistical inference (confidence intervals and hypothesis testing), assuming that $\varepsilon_{i} \sim N\left(0, \sigma^{2}\right)$.
4) Independence: All pairs $\varepsilon_{i}$ and $\varepsilon_{j}$ are (stochastically) independent.

The above-mentioned assumptions are met in this study.

## - MULTICOLLINEARITY

Another serious problem that may substantially impact the usefulness of a regression model is multicollinearity. This implies near-linear dependence among the regressors. Multicollinearity can have serious effects on the estimates of the regression coefficients and on the general applicability of the estimated model.

A good linear model results when the y (dependent) variables are highly correlated with the $x$ (independent) variables, but with as little as possible multicollinearity among the x variables.

From the example in chapter 2 , none of the x variables were significantly correlated, and therefore did not influence the model -see correlation matrix below. $\mathrm{X}_{2}$ and $\mathrm{X}_{4}$ were significantly correlated with the dependent variable.

The correlation matrix is:
Correlations

|  |  | Y | x1 | x2 | x3 | x4 |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| y | Pearson Correlation | 1 | . 266 | . $381{ }^{*}$ | -. 279 | . $459{ }^{*}$ |
|  | Sig. (2-tailed) |  | . 155 | *. 038 | . 136 | *. 011 |
|  | N | 30 | 30 | 30 | 30 | 30 |
| x1 | Pearson Correlation | . 266 | 1 | -. 105 | -. 009 | . 097 |
|  | Sig. (2-tailed) | . 155 |  | . 580 | . 962 | .611 |
|  | N | 30 | 30 | 30 | 30 | 30 |
| x2 | Pearson Correlation | $.381 *$ | -. 105 | 1 | -. 214 | . 074 |
|  | Sig. (2-tailed) | . 038 | 580 |  | . 256 | . 699 |
|  | N | 30 | 30 | 30 | 30 | 30 |
| x3 | Pearson Correlation | -. 279 | -. 009 | -. 214 | 1 | -. 176 |
|  | Sig. (2-tailed) | . 136 | . 962 | . 256 |  | .353 |
|  | N | 30 | 30 | 30 | 30 | 30 |
| x 4 | Pearson Correlation | . $459{ }^{*}$ | . 097 | . 074 | -. 176 | 1 |
|  | Sig. (2-tailed) | . 011 | . 611 | . 699 | . 353 |  |
|  | N | 30 | 30 | 30 | 30 | 30 |

*. Correlation is significant at the 0.05 level ( 2 -tailed).

Multicollinearity was in this example not a problem, but in many practical cases it may become a problem.

The following collinearity diagnostics are obtained from one of the simulations of this study where $\mathrm{n}=8$ and $\mathrm{p}=4$.

Collinearity Diagnostics ${ }^{\text {a }}$

| Model | Dimension | Eigenvalue | Condition Index | Variance Proportions |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  |  |  | (Constant) | x4 | x3 | x2 | x1 |
| 1 | 1 | 2.338 | 1.000 | . 02 | . 05 | . 03 | . 03 | . 03 |
|  | 2 | 1.190 | 1.402 | . 35 | . 00 | . 05 | . 04 | . 03 |
|  | 3 | . 906 | 1.607 | . 03 | . 16 | . 15 | . 03 | . 07 |
|  | 4 | . 438 | 2.312 | . 48 | . 38 | . 15 | . 09 | . 05 |
|  | 5 | . 129 | 4.260 | . 12 | . 41 | . 61 | . 80 | . 81 |

a. Dependent Variable: y

The condition index is the square root of the ratios of the largest eigenvalue to each successive eigenvalue. A condition index greater than 15 indicates a possible problem and an index greater than 30 suggests a serious problem with collinearity.

All the condition index values are smaller than 15 . This implies that there will not be a collinearity problem.

## - THE VARIANCE FOR $\widehat{\boldsymbol{\beta}}$

To obtain the narrowest possible confidence interval for $\beta_{\mathrm{j}}$, (and the maximum power in testing the hypothesis about $\beta_{\mathrm{j}}$, the variance for $\beta_{\mathrm{j}}$ must be minimized).

The variance for the estimated $\hat{\beta}_{\mathrm{j}}$, is used for the t -test and F -test and is the following:
$\operatorname{var}(\hat{\beta})=\sigma^{2}\left(X^{\prime} X\right)^{-1}$,
$\sigma^{2}=\operatorname{var}\left(y_{i}\right)$
$\widehat{\operatorname{var}}(\widehat{\boldsymbol{\beta}})=s^{2}\left(\boldsymbol{X}^{\prime} \boldsymbol{X}\right)^{-1}$ and
$\left(s^{2}\left(X^{\prime} X\right)^{-1}\right)_{i+1, i+1}=\widehat{\operatorname{var}}\left(\widehat{\boldsymbol{\beta}}_{i}\right)$
with $s^{2}$ the mean-square about regression (MSE)

## - THE MEAN-SQUARE ERROR FOR $\widehat{\boldsymbol{\beta}}$.

In statistics, the mean square error or MSE of an estimator is one of many ways to quantify the difference between an estimator and the true value of the quantity being estimated. MSE is a risk function, that corresponds to the expected value of the squared error loss or quadratic loss.

This is one of the important concepts that is used in the study, i.e. determining the error in multiple forward regression analysis. The mean-squared error is intimately related to the prediction accuracy. The mean-squared error for the full- as well as the forward model is determined for the different values of $n$ and $p$.

The MSE is the second moment (about the origin) of the error, and thus incorporates both the variance of the estimator and the bias. For an unbiased estimator, the MSE is the variance.

The mean-squared error of the estimator $\hat{\beta}$ in estimating $\beta$ is ${ }^{3}$ :

$$
\begin{align*}
\operatorname{MSE}(\widehat{\boldsymbol{\beta}}) & =\mathrm{E}\left[(\widehat{\boldsymbol{\beta}}-\boldsymbol{\beta})^{2}\right]=\operatorname{var}(\widehat{\boldsymbol{\beta}})+[\mathrm{E}(\widehat{\beta})-\beta]^{2} \\
& =\operatorname{var}(\widehat{\boldsymbol{\beta}})+[\operatorname{Bias}(\widehat{\beta}, \beta)]^{2} \\
& =(\widehat{\boldsymbol{\beta}}-\boldsymbol{\beta})^{`}(\widehat{\boldsymbol{\beta}}-\boldsymbol{\beta}) / \mathbf{p}^{4} \tag{1}
\end{align*}
$$

The red term is the variance, while the blue term is the squared bias. The format of the last part of the equation is used in the program of this study for the full and forward model.

The Gauss-Markov theorem implies that the least squares estimator has the smallest mean-square error for all linear estimators with no bias. However, there may exist a biased estimator with a smaller mean-squared error. Such an estimator would trade a little bias for a larger reduction in variance. Biased estimates are commonly used. Any method that shrinks or sets to zero some of the least square coefficients may result in a biased estimate.

The full linear regression model $\boldsymbol{y}=\boldsymbol{X} \boldsymbol{\beta}+\boldsymbol{\varepsilon} \quad \ldots$. (2) can be written as
$y=X_{k} \beta_{k}+X_{p-k} \beta_{p-k}+\varepsilon$
where the equation (3) is the linear equation of the full model and $\boldsymbol{X}_{\boldsymbol{k}} \boldsymbol{\beta}_{\boldsymbol{k}}$ is the reduced model.

There are two reasons ${ }^{5}$ why one may not be satisfied with the least squares estimates of the full model (eq. 2), with $\widehat{\boldsymbol{\beta}}=\left(\boldsymbol{X}^{\wedge} \boldsymbol{X}\right)^{-1} \boldsymbol{X}^{\boldsymbol{y}} \boldsymbol{y}$, namely:

- The first is prediction accuracy: the least square estimates often have low bias, but large variance. Prediction accuracy can sometimes be improved by shrinking

[^2]or setting some coefficients to zero. By doing so, a small amount of bias is sacrificed to reduce the variance of the predicted values, and hence may improve the overall prediction accuracy ${ }^{5}$.

Comment: The least square estimates of the parameters in the subset model have a smaller mean square error than the corresponding parameter estimates from the full model, when the deleted variables have regression coefficients that are smaller than the standard errors of their estimates in the full model ${ }^{6}$.

- The second reason is interpretation: With a large number of predictors, it is desired to determine a smaller subset that exhibits the strongest effects. In order to get more clarity, one may be willing to sacrifice some of the small details ${ }^{5}$.

From a more pragmatic point of view, most models are distortions of the truth, and hence are biased; picking the right model amounts to creating the right balance between bias and variance.

## - COEFFICIENT OF PARTIAL DETERMINATION

The coefficient of determination $R^{2}$ is a measure of the combined effects of all independent variables $X_{1} \ldots . X_{p}$, in the regression model in reducing the total variability. When considering whether or not to add another independent variable to the regression model, a different measure is needed. Such a measure is the coefficient of partial determination, which shows the marginal effect of a single variable associated with the regression model ${ }^{7}$.

For the regression model (2) with two independent variables, the coefficient of partial determination between $y$ and $x_{1}$, given $x_{2}$, already in the model is defined by:

$$
\begin{equation*}
\mathrm{r}^{2} \mathrm{Y}_{1,2}=\frac{\operatorname{SSE}\left(X_{2}\right)-\operatorname{SSE}\left(X_{1}, X_{2}\right)}{\operatorname{SSE}\left(X_{2}\right)} 8 \tag{4}
\end{equation*}
$$

where SSE is the error sum of squares.
This formula can be extended to the multivariate case. The square root of the coefficient of partial determination is called the coefficient of partial correlation. This and the extended formula are used in the program for the study.

The maximum $r$ is used within each step of the forward regression analysis, determining the next most important variable to be allowed into the model.

[^3]
## - FORWARD SELECTION VERSUS OTHER SUBSET SELECTION PROCEDURES

Forward regression analysis is a greedy algorithm that produces a nested sequence of modelsl ${ }^{9}$. In this sense it might seem sub-optimal compared to best-subset regression. However, there are several reasons why it might be preferred:

- Computational: for a large number of variables, one cannot compute the best subset sequence, but can always compute the forward selection (even when $p>$ n).
- Statistical: a price is paid in variance for selecting the best subset of each size; forward selection is a more constrained search, and will have lower variance , but perhaps more bias.

Comment: Bendel and Afifi (1977) have shown in a simulation that forward selection with an F-to-enter statistic at nominal $\propto=0.15$ produces a smaller population mean square residual than other more complex stopping rules.

The next part is also an abstract out of Hastie et al - The elements of Statistical learning. - p. 59.

Hastie et al.(2009) have a comparison of four subset-selection techniques on a simulated linear regression analysis dataset. They graphically pictured the meansquared error of the estimated coefficient $\widehat{\boldsymbol{\beta}}(\boldsymbol{k})$ at each step from the true $\boldsymbol{\beta}$ where k is the number of variables chosen from the subset model ( $k \in\{0,1,2 \ldots p\}$ ). He simulated $\mathrm{n}=300$ observations, $\mathrm{p}=31$ variables from a standard Gaussian distribution for 50 runs. 10 of the coefficients for each case were drawn at random from a normal $\mathrm{N}(0,0.4)$ distribution, with remaining coefficients equal to zero, and $\varepsilon \sim N(0,6.25)$.

[^4]The following graph has been obtained:

Figure A

Figure A shows the results of a small simulation study to compare best-subset regression with the simple alternative forward and backward selection. There are $\mathrm{n}=300$ observations on $\mathrm{p}=31$ standard Gaussian variables, with pairwise correlations that are all equal to 0.85 . For 10 of the variables, the coefficients are drawn at random from a $N(0,0.4)$ distribution, whilst the rest are zero. The noise $\sim N(0,6.25)$ results in a signal-to-noise ratio of 0.64 . Results are averages over 50 simulations. In the graph the mean-squared error of the estimated coefficient $\hat{\beta}(k)$ at each step from the true $\boldsymbol{\beta}$ is shown.

The performance of the different subsets is very similar, as is often the case. Included in the figure is forward regression. The forward stagewise regression takes longer to reach minimum error.

On the other hand, backward elimination starts with the full model, and sequentially deletes the predictor that has the least impact on the fit. Backward selection can only be used when $n>p$, while forward selection can always be used.

Different from this study, Hastie graphed the mean-squared error of the number of subset variables versus the mean-squared error at each stage of the selection.

In this study the mean-squared error is plotted against p (number of variables), n (numbers of observations) and $k$ (the number of variables selected) of each $n$ versus $p$ case, discovering the best $n$ versus $p$ ratios as well as the best number of $n$ and $p$ 's for the forward selection regression analysis.

Since these different procedures are widely used, knowledge of the distribution of the sample $R^{2}$ would be helpful in each case ${ }^{10}$. Berk (1978) has shown, however, that differences between procedures might not be significant in practice.

## - OTHER STUDIES ON FORWARD SELECTION

A study by Bendel(1977) slightly differs from this study. He studies the Comparison of Stopping rules in Forward Stepwise Regression. In his paper he uses the unconditional mean-square error of prediction as a criterion for comparing stopping rules used with the forward stepwise selection procedure in multivariate normal samples, based on simulations of 48 population correlation matrices. The $\mathrm{C}_{\mathrm{p}}$ statistic, "F to enter" ( $0.15<$ $\propto<0.25$ ), a rule which minimizes the sample criterion, and one which sequentially tests the equality of the population criterion $(0.25<\alpha<0.35)$ were used. For these rules, the criterion seldom differs by more than $3 \%$, although there are considerable differences between these and some other rules.

For the prediction problem in Bendel's study, the regression equation is used to predict the $y$ value of a randomly chosen element $\left(y_{0}, \mathbf{x}_{0}\right)$ of the population. When $\hat{y}_{(q)}\left(\mathbf{x}_{0}\right)$ is used as an estimator of $y_{0}$, the unconditional mean-square error of the prediction is defined as:

$$
\operatorname{UMSE}_{(\mathrm{q})}=\mathrm{E}\left\{\hat{y}_{(\mathrm{q})}\left(\mathbf{x}_{0}\right)-\mathrm{y}_{0}\right\}^{2}
$$

where the expectation is taken over all the random variables, including the "new" observation $\left(y_{0}, \mathbf{x}_{0}\right)$, as well as the independent variables of the regression sample. The criterion UMSE was used by Stein [23] who employed the same basic model as described. Afifi and Elashoff [1] used this criterion to establish relative efficiencies in various missing value techniques.

In another study by Wilkinson (1981), he simulated upper critical values of the distribution of the sample squared multiple correlation coefficient under forward selection regression when the population multiple correlation is zero and the predictors are mutually independent.

His simulation involved sampling of a dependent variable and predictors from a standard spherical multi-normal distribution. Sample correlation matrices were generated directly from a standardized Wishart distribution using an algorithm from Odell and Feiveson(1966).

Normal numbers were generated by a subroutine FA03A of the Harwell Subroutine Library (1973). $R^{2}$ values were generated by the abbreviated Gauss-Doolittle method with forward selection of the predictors (Draper and Smith 1966, p 178). Forward stepping was continued on each sample until the F-to-enter rule was not met by any variable remaining to be selected. (Barr et al. 1976; Dixon 1979; Nie et al. 1975; denote this stopping rule as F-to-enter). Each regression was computed for at least 500 samples and continued in additional blocks of 100 samples until three successive blocks yielded the same $R^{2}$ value to two decimal places for both the $95^{\text {th }}$ and $99^{\text {th }}$

[^5]percentage points of the sample distribution. Using this procedure, test runs on known values (when $\mathrm{F}=0$ ) yielded the upper tail values correct to two significant digits reported in this article.

The values calculated in Wilkinson's study are shown as follows:

Table A: Upper Five Percent Points of the Distribution of the Sample Squared Multiple Correlation ( $\times 1 \mathbf{0}^{2}$ ) Under Forward Selection From $m$ Variables, n Observations, and F-to - enter Value.

The tables (A \& B) of simulation results allow graphical interpolation with respect to any of the parameters ( $\mathrm{F}, \mathrm{m}$ : the number of variables selected, and n : number of observations) to within a 0.01 precision in the $\mathrm{R}^{2}$ values. The use of forward selection with these tables allows the researcher to test the null hypothesis that the population squared multiple correlation is zero when the number of variables in a subset regression has not been specified prior to the data analysis.

Another study on Forward selection of Explanatory variables is done by Blanchet et al. (2008):

This paper proposes a new way of using forward selection of explanatory variables in regression or canonical redundancy analysis.

Ecologists are known to sample a large number of environmental variables to try to better understand how and why species and communities are structured. They are often faced with the problem of having too many explanatory variables to perform standard regression or canonical analysis. One method very often used for selecting variables in ecology, is forward selection. It presents the great advantage of being applicable even when the initial data set contains more explanatory variables than sites, which is often the case in ecology.

However, forward selection is known to overestimate the amount of explained variance, which is measured by the coefficient of multiple determination ( $\mathrm{R}^{2}$; Diehr and Hoflin 1974, Rencher and Pun 1980). Another problem with forward selection is a highly inflated Type I error.

Correcting these problems will greatly improve the performance of this very useful method in ecological modelling. To prevent this problem, they proposed a two-step procedure. Firstly, a global test using all explanatory variables is carried out. If and only if, the global test is significant, one can proceed with forward selection. To prevent overestimation of the explained variance, the forward selection has to be carried out with two stopping criteria: (1) the usual alpha significance level and (2) the adjusted coefficient of multiple determination $\left(R^{2}\right)$ calculating using all explanatory variables.
(Adding unimportant variables to an already well-fitted model has practically no impact on the explained variance measured by $R_{a}{ }^{2}$. Thus the use of $R_{a}{ }^{2}$ as an additional stopping criterion is a good choice in forward selection procedure).

When forward selection identifies a variable that brings one or the other criterion over the fixed threshold, that variable is rejected and the procedure is stopped. This improved method is validated by simulations involving univariate and multivariate response data.

The table below is also an abstract out of Blanchet's article.
Table C shows the percentage of simulations in which all the variables are used to create the univariate or multivariate response variable(s), and only those are retained by the forward selection procedure.

An ecological example is presented in this article as well.
Whitney (2000) did a study on: Unsupervised Forward Selection: A method for eliminating Redundant variables.

An unsupervised learning method is proposed for variable selection and its performance is assessed using three typical QSAR data sets. The aims of this procedure are to generate a subset of descriptors from any given data set in which the relevant variables are relevant, redundancy is eliminated and multicollinearity is reduced. Continuum regression, an algorithm encompassing ordinary least squares regression, regression on principal components, and partial least squares regression, was used to construct models from selected variables. The variable selection routine is shown to produce simple, robust, and easily interpreted models for chosen datasets.

Another study is done by Stodden(2006) where she studied Model Selection when the number of variables exceeds the number of observations i.e. $\boldsymbol{n}<\boldsymbol{p}$.

This classical multivariate linear regression problem assumes $p$ predictor variables $X_{1}$, $X_{2} \ldots . X_{p}$ and a response vector $y$, each with $n$ observations, and a linear relationship between the two. $\boldsymbol{y}=\boldsymbol{X} \boldsymbol{\beta}+\boldsymbol{\varepsilon}$, where $\boldsymbol{\varepsilon} \sim \mathrm{N}\left(0, \sigma^{2}\right)$. This thesis found that when $\mathrm{n}<\mathrm{p}$, there is a breakdown point for standard model selection schemes, such that model selection only works well below a certain critical complexity level depending on $\frac{n}{p}$. This notation is applied to some standard model selection algorithms (Classical Forward Stepwise, Forward Stepwise with False Discovery Rate thresholding, Lasso, LARS, and Stagewise Othogonal Pursuit) in the case where $\mathrm{n} \ll$ p.

The notation of the Phase 1 Diagram is borrowed from the signal processing and statistical physics to discover that:

1) The breakdown point is well-defined for random $X$-models and low noise
2) Increasing noise shifts the breakdown point to lower levels of sparsity, and reduces the model recover ability of the algorithm in a systematic way and
3) Below breakdown, the size of coefficient errors follows the theoretical error distribution for the classical linear model.

Stodden used threshold algorithms for the Classical Forward Stepwise, the Forward Stepwise and the Lasso and LARS methods. She determined that the threshold-toenter for Classical Stepwise was set at $\sqrt{2 \log (p)}$, implying that the absolute value of the t-statistic for variables under consideration for inclusion in the model must be greater than $\sqrt{2 \log (p)}$. She used the number of variables, $\mathrm{p}=200$. The threshold-to-enter would then be 3.25 .

Figure B: This Empirical Phase Diagram for Forward Stepwise illustrates where the underlying sparse model is recovered using the Forward Stepwise Algorithm, with the number of variables, p, fixed at 200 and the noise $\varepsilon \sim N(0,16)$. Variables were greedily added to the model until no remaining t-statistic was greater than $\sqrt{2 \log (p)}$ in absolute value. The phase transition is striking: there is a very sharp drop-off below which the algorithm recovers the model with near zero error, and above which the model is unrecoverable. As with the theoretical phase transition diagram in Figure C, along the $x$-axis the level of underdeterminedness decreases, and along the $y$-axis the level of
sparsity of the underlying model increases. Each colour indicates a different median normilized $I_{2}$ error of the coefficients $\frac{|\widehat{\beta}-\beta|^{2}}{|\beta|^{2}}$ over 30 realizations
where $\mathrm{l}_{\mathrm{i}}$-norm is defined for a vector $\mathrm{x}=\left[\mathrm{x}_{1}, \mathrm{x}_{2} \ldots \mathrm{x}_{\mathrm{n}}\right]$ :
and where $\left|x_{0}\right|=\#\{$ non zeros in $x\}$
Using this to define the sparsity solution gives the following problem:
$\min _{\beta}|\beta|_{0}$ s.t. $y=\boldsymbol{X} \boldsymbol{\beta}$
This is intuitively compelling - literally choosing the sparsest solution.
The normalized root mean-square error (nRMSE) $=\frac{|\widehat{\beta}-\beta|^{2}}{|\beta|^{2}}$
The results are comparable across models built with different problem sizes and noise levels. The median nRMSE over instances at given values for $k, n$ and $p$ have been reported to indicate the algorithm performance.

Figure C: Theoretical Phase Transition Diagram: theoretical threshold at which equivalence of the solutions $I_{1}$ and $I_{0}$ optimization problem breaks down. The curve delineates a phase transition from the lower region where the equivalence holds, to the upper region, where it seems to require combinational search to recover the optimal sparse model. Along the $y$-axis the level of underdeterminedness decreases, and along the $y$-axis the level of sparsity of the underlying model increases.

Stodden also determined the nRMSE for Pre-Breakdown Region for the Classical Forward Stepwise, with $\delta=\frac{n}{p}=0.5$ (this is also one of the n versus p cases in this study).

Figure D

Figure D: nRMSE for Pre-Breakdown Region for the Classical Forward Stepwise; $\delta=\frac{n}{p}, \mathrm{p}=200$. Results for each of $\sigma \in\{0,1,2,4,6,12,16\}$ are displayed. The median relative error is determined over 1000 replications. Although the actual nRMSE rates are low compared to the other algorithms in this study, the breakdown points occur earlier, i.e. at smaller values of $\rho$.

Stodden mentioned that to expand the analysis beyond $\delta=\frac{n}{p}=0.5$ would be useful, since the nature of the breakdown in performance, depends on the level of indeterminacy $\delta$.

Extending the experiments to a much larger $p$ would also allow one to draw empirical conclusions about how the level of indeterminacy affects the breakdown point.

## - NUMBER OF VARIABLES AND OBSERVATIONS

In this study some attention is paid on the estimating of the regression coefficients in the cases where the number of variables exceeds the number of observations - as studied by Stodden. The accuracy of the model with different n and p values is determined.

Radchenko(2011) on the other hand only focused on variable selection methods in regression situations where the number of predictors ( $\mathfrak{p}$ ) is large relative to the number of observations ( n ). Two commonly applied variable selection approaches are the Lasso, which computes highly shrunk regression coefficients, and Forward Selection, which uses no shrinkage. They propose a new approach, "Forward-Lasso Adaptive Shrinkage" (FLASH), which includes the Lasso and Forward Selection as special cases, and can be used in both the linear regression and the Generalized Linear Model domains.

As with the Lasso and Forward Selection, FLASH iteratively adds one variable to the model in a hierarchical fashion but, unlike these methods, at each step adjusts the level of shrinkage so as to optimize the selection of the next variable. They first present FLASH in the linear regression fitting and show that it can be fitted using a variant of the computationally efficient LARS algorithm. Then they extend FLASH to the GLM domain and demonstrate, through numerous simulations and real world data sets, as well as some theoretical analysis, that FLASH generally outperform many competing approaches.

## - SHRINKING APPROACHES

Hastie et al.(2009) made a study of the shrinkage methods as well. Subset selection is a method of retaining a subset of the predictors and discarding the rest. It produces a model that is interpretable and has possibly lower prediction error than the full model. However, because it is a discrete process - variables are either retained or discarded it often exhibits high variance, and so doesn't reduce the prediction error of the full model. Shrinkage methods are more continuous, and do not suffer as much from high variability.

He compared the different methods, by comparing estimated prediction error curves.

The following graphs, (Figures (E)) show the estimated prediction error curves and their standard errors for the various selection and shrinkage methods. Each curve is plotted as a function of the corresponding complexity parameter for that method. The horizontal axis has been chosen so that the model complexity increases as we move from left to right. The estimates of prediction error and their standard errors were obtained by tenfold cross-validation. The least complex model within one standard error of the best is chosen, indicated by the purple vertical broken lines.

Figures (E)

These different methods are only shown here but this is beyond the scope of this dissertation. It is just shown to take note of.

## Chapter 4

## DESIGN OF THE SIMULATION STUDY

In this chapter the parameters used in the SAS IML programme are given, and the procedures and steps of the program, is described. The references referred to, is given in chapter 5, "Steps, following the Statistics of the study", simulation results followed in chapter 6, conclusions and graphs in chapter 7, as well as the program, in chapter 11 - the appendix.

The forward selection regression model is used for this investigation. The full model is also used for comparison in this study.

The references marked in red referer to the program and / or printout.
In this study, simulations of 10000 runs $(\operatorname{sim}=10000)^{11}$ for the chosen $n$ and $p$ values are done for each of the full- and forward multiple regression analysis. Firstly a few modules in SAS IML are defined, followed by the main program. Then the full regression model is done followed by the forward selection model. The last part of the program consists of a few calculations.

The parameters chosen for the study are the following:
The number of variables $(p)$ used in the regression, is chosen to range from 4 to 20 (integer numbers). This is the number of variables to be included in the full model for each case. In the forward selection model, the best $k(k<p)$ variables are chosen. For each of the $p=4 \ldots .20^{12}$ the values for $n$, which is the number of observations is chosen to be $0.5 p, p, 2 p$ and $4 p^{13}$. In the case where $n=0.5 p$ and $n$ is not an integer, $n$ was rounded up to the next larger integer.

The x values are then generated from a normal distribution ${ }^{14}$ where $\mathrm{x}_{\mathrm{i}} \sim N\left(\boldsymbol{\mu}_{x}, \boldsymbol{\Sigma}_{X}\right)$ and $\mu_{x}=\{0\}^{15}$ and
$\boldsymbol{\Sigma}_{\boldsymbol{X}}=\left(\begin{array}{ccc}1 & \cdots & 0.5 \\ \vdots & \ddots & \vdots \\ 0.5 & \cdots & 1\end{array}\right)=0.5\left(I_{p}+J_{p}\right)^{16} \quad$ where $I_{p}=\left(\begin{array}{ccc}1 & \ldots & 0 \\ \vdots & 1 & 0 \\ 0 & \ldots & 1\end{array}\right) \quad$ and $J_{p}=\left(\begin{array}{ccc}1 & \ldots & 1 \\ \vdots & 1 & \vdots \\ 1 & \ldots & 1\end{array}\right)$
$\varepsilon_{i}$ are also generated from a normal ${ }^{17}$ distribution with $\varepsilon_{i}$ independent $\sim N(0,4)^{18}$ distributed. The equation for the linear regression model is $\mathrm{y}=\boldsymbol{X} \boldsymbol{\beta} \boldsymbol{\beta} \boldsymbol{\varepsilon}$.

The $\beta_{i}$ (where p is even) values are assigned $\beta_{\mathrm{i}}=1$; for the first half of the total number of $x_{i}$ 's (these are the first $\frac{p}{2}$ values). If the $p$ value (the total number of $x$ 's) is an odd

[^6]number, then the first $\frac{p+1}{2}$ values were assigned to the $\beta_{i}=1$ value and the remaining $\beta_{i}$ $=0$.

Thus $\beta=\left[\begin{array}{l}1 \\ 1 \\ \vdots \\ 0 \\ 0\end{array}\right] \quad$ for the first $\frac{p}{2}$ or $\frac{p+1}{2} \beta_{i}=1$ 's and the rest of $\frac{p}{2} \beta_{i}^{\prime} s=0$ 's. ${ }^{19}$
That means that half of the number of variables i.e. the first $\frac{p}{2}$ or $\frac{p+1}{2}$, should be included in the model when doing forward selection. In this study we determine the probability of a correct classification as well.

The results and conclusions of this study are mostly illustrated in the graphs presented in Chapter 7.

## a. The full model ${ }^{20}$

The full linear regression model $\boldsymbol{y}=\boldsymbol{X} \boldsymbol{\beta}+\boldsymbol{\varepsilon}$ is used to determine the least squares estimates of the full model with $\widehat{\boldsymbol{\beta}}=\left(\boldsymbol{X}^{\top} \boldsymbol{X}\right)^{\mathbf{- 1}} \boldsymbol{X}^{\prime} \boldsymbol{y}^{21}$

The parameters were chosen as above mentioned.
The test for significance of regression is a test to determine if there is a linear relationship ${ }^{22}$ between the response variable ( y ) and the regressor variables $\mathrm{x}_{1}, \mathrm{x}_{2} \ldots \mathrm{x}_{\mathrm{p}}$. This test is done in the analysis for each simulation and each selected $n$ and $p$ case ${ }^{23}$.

This procedure is often thought of as an overall or global test of model adequacy. The appropriate hypotheses are:

$$
\begin{aligned}
& \mathrm{H}_{0}: \beta_{1}=\beta_{2}=\cdots \cdot \beta_{p}=0 \\
& \left.\mathrm{H}_{1}: \beta_{\mathrm{j}} \neq 0 \quad \text { (for some } \mathrm{j}\right)
\end{aligned}
$$

Rejection of the null hypothesis implies that at least one of the regressors $\mathrm{x}_{1}, \mathrm{x}_{2} \ldots \mathrm{x}_{\mathrm{p}}$. contributes significantly to the model.

The test procedure is a generalization of the analysis of variance used in simple linear regression. The total sum of squares (SST) ${ }^{24}$ is portioned into the sum of squares due to regression, (SSreg) ${ }^{25}$ and the residual sum of squares (SSE) ${ }^{26}$.

Thus SST = SSreg + SSE

$$
\text { MSreg }=\text { SSreg } / p^{27}
$$

[^7]MSE $=$ SSE $/(n-p-1)^{28}$
The $R^{2}=$ SSreg $/ S S T^{29}$ is called the coefficient of determination.
The full regression model is applied to the simulated data. The F-probability ${ }^{23}$ is determined for each simulation and each case ( $n$ and $p$ ).

The F-probabilities are grouped into the classes $p<0.01,0.01<p<0.05$ and $p>0.05$ for each simulation, $n$ and $p$ case. The proportion counts of each $n$ and $p$ case (over 10000 simulations) is determined. ${ }^{30}$

See table 5, graphs 10 and 11 for the results on this study.
The test for the Hypothesis $\mathrm{H}_{0}: \beta_{j}=0$ for each $\beta_{j}$ and

$$
H_{1}: \beta_{j} \neq 0 \text { for each } \beta_{j} \text { is done in this example. }
$$

This test should actually be tested against the real $\beta_{j 0}$ values, assigned in the program and not $\beta_{j}=0$ (for all $\beta_{j}$ ) as done here.

This test here is actually done for testing the SAS IML program versus the SAS PROC REG program: ${ }^{31}$

The right test for the Hypothesis $\mathrm{H}_{0}: \beta_{j}=\beta_{j 0}$ for each $\beta_{j}$ and

$$
\mathrm{H}_{1}: \beta_{\mathrm{j}} \neq \beta_{j 0} \text { for each } \beta_{j} \text { for } \mathrm{j}=0 \ldots \mathrm{p}
$$

where the test statistic should be:

$$
t_{0}=\frac{\hat{\beta}_{j}-\beta_{j 0}}{\operatorname{se}\left(\hat{\beta}_{j}\right)}
$$

where the null hypothesis $\mathrm{H}_{0}: \beta_{j}=\beta_{j 0}$ for each $\beta_{j}$ should be rejected if:

$$
\left|t_{0}\right|>t_{\frac{\alpha}{2}, n-p-1}
$$

The mean-squared error is also determined and compared to the mean squared-error for the forward model. Results, on this are seen in table 4 and graphs $3,5,8 \& 9$.

The other calculations follow in chapter 5 .

[^8]
## b. The Forward selection model ${ }^{20}$

The full linear regression model $\boldsymbol{y}=\boldsymbol{X} \boldsymbol{\beta}+\boldsymbol{\varepsilon}^{32}$ can be written as $\boldsymbol{y}=\boldsymbol{X}_{\boldsymbol{k}} \boldsymbol{\beta}_{\boldsymbol{k}}+\boldsymbol{X}_{\boldsymbol{p}-\boldsymbol{k}} \boldsymbol{\beta}_{\boldsymbol{p}-\boldsymbol{k}}+\varepsilon \quad$ where p is the number of variables and k the numbers of variables selected in the forward selection.

Then, the least-squares estimate of $\boldsymbol{\beta}_{\boldsymbol{k}}$ is $\widehat{\boldsymbol{\beta}_{\boldsymbol{k}}}=\left(\boldsymbol{X}_{\boldsymbol{k}}{ }^{`} \boldsymbol{X}_{\boldsymbol{k}}\right)^{-\mathbf{1}} \boldsymbol{X}_{\boldsymbol{k}}{ }^{`} \boldsymbol{y}^{21}$
Firstly the variable maximum correlated to the $y$-variable is determined. ${ }^{33}$
Test the significance of the variable. ${ }^{34}$
A counter matrix is calculated to determine which variables in- or excluded from the model. ${ }^{35}$

The coefficients of partial correlation are determined. ${ }^{36}$
The maximum $r$ is determined. ${ }^{37}$
This process is repeated until there are no significant variables left for inclusion into the model. ${ }^{38}$

The final $\widehat{\boldsymbol{\beta}_{\boldsymbol{k}}}$ for the forward model is determined. ${ }^{39}$
The mean-squared error of the forward- and full models is determined. ${ }^{40}$
The other calculations which are used for this study be follow in the program, chapter 11 - the appendix.

[^9]
## Chapter 5

## STEPS, FOLLOWING THE STATISTICS OF THIS STUDY (printout)

This chapter consists of the computer printout for 1 simulation. It actually differs a bit from the program in the appendix. The program in the appendix is for the 10000 simulation with the different cases of $n$ and $p$. It is also the full program of the study.

The statistical analysis in IML is compared with the statistics in the SAS (proc reg) printout here. The parameters here are set the same as in chapter 7 (the simulation study), but with only 1 simulation here. So it can be compared with SAS (proc reg)
$\mathrm{n}=30$ and $\mathrm{p}=8$ is used here.
The SAS IML programme
(See the references on the red letters. It refers back to the footnotes used in Chapter 4)

## Chapter 6

## SIMULATION RESULTS

The properties of forward regression will be evaluated and compared to the full model in terms of the following:

- The probability that irrelevant variables $\left(\beta_{j}=0\right)$ will be included in the model;
- The probability that relevant variables $\left(\beta_{j}=1\right)$ will be included from the model;
- The mean-squared error of the regression coefficients;
- The relative frequencies of the F - probability in the full model is also illustrated.

Table 1 represents the number of $x$ 's included in the model with each simulation. All the cases therefore add up to 10000 , the number of simulations, times the number of variables.

Table 2 represents the total number of $b_{j} s=1$ being correctly classified, whereas table 3 , represents the total number of $b_{j}$ 's=0 being incorrectly classified.

Histogram graphs of table 2 and 3 are given in chapter 7, graphs 1 and 2 .
Table 4 represents the mean-squared error for the full- and forward selection models.
Table 5 represents the F-probability counts of the full model.

The full regression model $\boldsymbol{y}=\boldsymbol{X} \boldsymbol{\beta}+\boldsymbol{\varepsilon}$ is used to determine the least squares estimates of the full model with $\widehat{\boldsymbol{\beta}}=\left(\boldsymbol{X}^{`} \boldsymbol{X}\right)^{\mathbf{- 1}} \boldsymbol{X}^{`} \boldsymbol{y}^{81}$. This is applied to the simulated data. The Fprobability is determined for each simulation and each case ( n and p ).

That is, the hypothesis $\mathrm{H}_{0}: \beta_{1}=\beta_{2}=\cdots \cdot \beta_{p}=0$ is being tested and the $\mathrm{F}_{0}$ statistic is being computed. The $\mathrm{H}_{0}$ hypothesis is being rejected if:

$$
F_{0>}>F_{\alpha, p, n-p-1}
$$

The F-probabilities is grouped into the classes $p<0.01, \quad 0.01<p<0.05$ and $p>0.05$. The proportion of the counts within the classes $p<0.01, \quad 0.01<p<0.05$ and $p>0.05$ for each n and p case (over 10000 simulations) is determined.

Discussions of the table above are given and represented in graphs 10 to 11.

[^10]
## Chapter 7

## CONCLUSIONS AND GRAPHS

Graph 1. This represents the probabilities for $x_{I}$ 's being correctly classified where $\beta_{\mathrm{J}}=1$ for the forward selection analysis.

See Table 2 in Chapter 6 for data.
Each of the probability cases (for each $n$ versus $p$ case), is determined by the total number of $x_{i}^{\prime}$ 's being correctly classified (where $\beta_{j}=1$ ) divided by the total number of simulations, which is multiplied by the number of variables.

From the above-mentioned graph it is evident that the probabilities (for $\mathrm{x}_{\mathrm{i}}$ 's being correctly classified) form 4 distinct groups, i.e. for each group, $n=0.5 p, p, 2 p$ and $4 p$ they form different probability groups. For a multiple linear forward regression analysis, the best probability for the $x_{i}$ 's to be correctly classified lies within the classification of the $n$ $=4 \mathrm{p}$ group.

From the above one may deduce that in the situation presented by the present simulation, the probability for a correct classification is $>40 \%$ for $n=4 p$. For the cases where $n=4 p$ and $n>36$ (case 16), the probability of a correct classification $>60 \%$. For the cases where $n=4 p$ and $n>68$ (case 47), the probability of a correct classification is more than $80 \%$.

In order to obtain better accuracy in multiple regression it should be evident that $n>4 p$ and $n>36$. The probability of a correct classification will then be higher than $60 \%$.

Looking at this graph (with specified conditions) it would not be recommended that $\mathrm{n}=$ 0.5 p , where $\mathrm{n} \leq 20$. The probability of a correct classification is smaller than $20 \%$, which is not advisable.

Graph 2. This represents the probabilities for $x_{i}$ 's being misclassified where $\boldsymbol{\beta}_{\mathrm{j}}=\mathbf{0}$.

See Table 3 in Chapter 6 for data.
Each of the probability cases is determined by the total number of $x_{i}$ 's being misclassified (where $\beta_{j}=0$ ) divided by the total number of simulations, which is multiplied by the number of variables.

From the above one may deduce that in the situation presented by the present simulation forms 2 groups for the cases higher than $19(0<j<p)$. This is applicable for the groups, $n=0.5 p, p$ and $2 p$ forming one group and $n=4 p$ forming the other probability group. For a multiple, linear forward regression analysis, the lowest probability for the $x_{i}$ 's to be misclassified lies within the classification of the $n=4 p$ group; especially for the cases higher than $16(p>9)$.

The misclassification for a multiple forward regression for $n=4 p$ is less than $10 \%$. From this graph it is also clear that the misclassification for $p>10$ (cases $>19$ ) is slightly less than the rest of $n=4 p$.

To obtain better accuracy in multiple forward regression, it is recommended that $n>4 p$ and $\mathrm{n}>40$.

Each test was done normally at $\alpha=0.05$, but the actual significance level seems to be between 0.08 and 0.12 depending on n and p . This indicates that forward selection is a reliable method to use, but one may have to adjust the significance level.

## Different graphs of the mean-squared error of $\widehat{\beta}$ is presented below: (See table 4)

Graph 3. The mean-squared error for $\widehat{\beta}$ from $\boldsymbol{\beta}$ for the full regression model versus $\boldsymbol{n}$ for the different values of $\boldsymbol{p}$.

From 10000 simulations, when $n=2 p$ and $n=4 p$, the mean-squared error of the estimated coefficient $\widehat{\boldsymbol{\beta}}$ is determined for the full regression model. The full regression model can however not be done for the cases $n=0.5 p$ as $\left(X^{\prime} X\right)$ is singular and the inverse does not exist. For $\mathrm{n}=\mathrm{p}$ an exact fit would be obtained.

From graph 3 it is clear that the mean-squared error of the estimated coefficient $\widehat{\boldsymbol{\beta}}$ for the full regression model has an exponential curve when both $p$ and $n$ increase simultaneously. The blue and the green curves decrease, when $n=2 p$ and $n=4 p$
increase respectively. There is not much difference in the mean-squared error of $\widehat{\boldsymbol{\beta}}$ between the curves when $n=2 p$ and $n=4 p$ for the same $p$ value.

The multilpe linear regression for the full model is more accurate for higher $n$ values. The mean-squared error for the cases where $n=4 p$ is less and therefore more accurate.
(table 4)

Graph 4. This graph represents the mean-squared error of $\widehat{\boldsymbol{\beta}}$ from $\boldsymbol{\beta}$ for the forward selection model versus $\mathbf{n}$, for different values $\mathbf{p}$.

| For $n=4 p:$ | orange: $\quad p$ is odd. <br> red: |
| :--- | :--- |
| For $n=2 p:$ | light blue: $p$ is even <br> dark blue: $p$ is even. |
| For $n=p:$ | dark green: $p$ is odd. <br> light green: $p$ is even. |
| For $n=0.5 p:$ | brown: $\quad p$ is odd. <br> yellow: $p$ is even. |

For each of the $n$ versus $p$ ratio's the mean-squared error graphs form 4 different trends. For each of the $n$ versus $p$ ratio curves there are two disjoint curves. The reason for this is the following:
$\boldsymbol{\beta}_{\boldsymbol{j}}=1$ is chosen for the first half of the $\boldsymbol{\beta}$ values and the remaining, $\boldsymbol{\beta}$ 's $=0$ where p is even. This results in one group, whereas the cases where $p$ is an odd number, the first $\frac{p+1}{2}, \boldsymbol{\beta}$ 's = 1 and the remaining $\boldsymbol{\beta}$ ' $s=0$, results in another group.

From Graph 4 the minimum sample size ( $n$ ) for a specified $p$ and the minimum sample size for a certain $n$ versus $p$ ratio (under normal conditions) can be determined.

The sample size, n must not be too small, otherwise the estimator will not be correct. Only a certain number of variables are kept in the model (k) for the forward selection, which is often much less than $p$ - this is shown in graph 7.

In all the cases the mean-squared error decreases as n increases. To obtain a more accurate forward regression model, it is therefore recommended that $n=4 p$.

It is not advisable that $n=0.5 p$ and that $n$ is too small. If this were the case, it is advised that the sample size n be increased, i.e. n must be greater than 10. (table 4)

Graph 5. This graph represents the mean-squared error of $\widehat{\boldsymbol{\beta}}$ for the full regression model versus $p$, for different values of $n$.

The mean-squared error for the estimated coefficient $\hat{\beta}$ from the true $\boldsymbol{\beta}$ for the full model versus $p$, where $n>p+1$ is represented in the graph above.

The graph formed 2 curves, the one for $n=2 p$ and the other one for $n=4 p$. It forms exponential curves, similar than the plot of mean-squared error for the estimated coefficient $\hat{\beta}$ versus n .

For an accurate forward model $n=4 p$ and $p>5$ would be advisable. (table 4)

Graph 6. This graph represents the mean-squared error of $\widehat{\beta}$ for the forward selection model versus $p$, for different values of $n$.

The 4 four different n versus p groupings can be shown as:
For $n=4 p$ : orange: $p$ is odd.
red: $\quad p$ is even.
For $n=2 p$ : light blue: $p$ is odd.
dark blue: $p$ is even.
For $n=p$ : dark green: $p$ is odd.
light green: $p$ is even.
For $n=0.5 p$ : brown: $p$ is odd.
yellow: $p$ is even.
The mean-squared error is intimately related to prediction accuracy. The lower the mean-squared the more accurate the model and estimates.

The three groups, $n=p, n=2 p$ and $n=4 p$ is grouped together and the group $n=0.5 p$ from a group on its own. It is again advisable that $n \neq 0.5 p$ is not used, especially when $\mathrm{p}<20$ (table 4).

The following graph illustrates a different point of view (when compared with Graph 6) when the mean-squared error is plotted against $k$, the number of variables in the forward selection for different values of $n$.

Graph 7. The mean-squared error of $\widehat{\beta}$ for the forward selection model versus $\mathbf{k}$ (the number of variables to be in the model) for different values of $\mathbf{n}$.

The graph forms similar patterns than the graph of the mean-squared error of $\widehat{\beta}$ (graph 6 ) versus $p$. The different colour groups represent the groups where $n=0.5 p, p, 2 p$ and 4p.

Because $k$ variables are selected out of the $p$ values in forward regression analysis, the outcome of the forward selection model is determined by $k$, the number of variables included in the model. For a more accurate forward selection, $k$ must be bigger than 4 and $n=2 p$ or $4 p$. Thus $p$ must be greater than 4 as well.

To obtain a more accurate forward regression model, it is again recommended that $\mathrm{n}=$ 4p. (table 4)

Graph 8. The graph represents the differences between the forward- and full model of the mean-squared error of the estimated coefficient, $\widehat{\boldsymbol{\beta}}$. The independent variable here is the sample size ( n ).

This graph shows the difference in mean-squared error of the full- versus the forward model. The independent variable is here the number of variables ( $n$ ).

For the cases where $n=2 p$ (comparing the red and blue graph) the forward model has a lower mean-squared error for $\widehat{\boldsymbol{\beta}}$ than the full model, (especially for low $n$ values). The forward model is therefore more accurate than the full model in this case.

For the cases where $n=4 p$ (comparing the orange and green graph) the two graphs do not differ much in mean-squared error values for $\widehat{\boldsymbol{\beta}}$ especially where $\mathrm{n}>60$.

The full regression model can however not be done for the cases $n=0.5 p$ as $\left(X^{\prime} X\right)$ is singular and the inverse does not exist. For $n=p$ an exact fit would be obtained. In those cases the forward model can only be used.

To obtain better accurate models the full- as well as the forward model is suggested for the case where $n=4 p$. For the case where $n=2 p$ the forward model is preferred.
(table 4)

Graph 9. The graph represents the differences between the forward- and full model of the mean-squared error of the estimated coefficient, $\widehat{\boldsymbol{\beta}}$. The independent variable here is the sample size (p).

This graph shows the difference in mean-squared error of the full- versus the forward model. The independent variable here is the number of variables (p).

The graph shows similar patterns than graph 8 . For the cases where $\mathrm{n}=2 \mathrm{p}$ (comparing the red and blue graph) the forward model has a lower mean-squared error for $\widehat{\boldsymbol{\beta}}$ than the full model, (especially for low p values). The forward model is therefore more accurate than the full model in this case.

For the cases where $\mathrm{n}=4 \mathrm{p}$ (comparing the orange and green graph) the two graphs do not differs much in mean-squared error values for $\widehat{\boldsymbol{\beta}}$. Both models is good here.

For the cases where $\mathrm{n}=0.5 \mathrm{p}$ and $\mathrm{n}=\mathrm{p}$, the full model could not be determined, because ( $X^{\prime} X$ ) is singular and the inverse does not exist.

To obtain better accurate models the full- as well as the forward model is suggested for the case where $\mathrm{n}=4 \mathrm{p}$. In practise it often happened that the most important variables would be chosen, then the forward model is the preferable model, especially when $\mathrm{n}=2 \mathrm{p}$.

The following two graphs show the proportion of F-probability counts within the three classes $\mathbf{P}>0.05,0.01<P<0.05$ and $P<0.01$ over the 10000 simulations of the full model for the cases where $n=2 p$ and $n=4 p$ (for each $n$ and $p$ case).

Graph 10. This graph represents the case where $\mathbf{n}=\mathbf{2 p}$.lt is shown in green, red and blue respectively.

This refers to table 5.
The F-probability for the full model is determined for each simulation and each case ( n and p). 10000 simulations are done for this study. For each simulation the Fprobability is grouped into one of the classes, $p>0.05,0.01<p<0.05$ and $p<0.01$. The average F-probability counts over 10000 are determined and shown in the graph as a proportion.

Out of this graph it is clear that the multiple regression analysis for the full model is more significant for the larger n (also p ) values. It is advisable that n must be larger than 26 for the case where $\mathrm{n}=2 \mathrm{p}$. The model is significant, as 0.01 level is always achieved.

Graph 11. This graph represents the case where $\mathrm{n}=4 \mathrm{p}$. It is shown in green, red and blue respectively.

This refers to table 5.
It is the average F-probability counts for the classes $p>0.05,0.01<p<0.05$ and $p<0.01$ for $n=4 p$ over 10000 simulations The full regression model can however not be done for the cases $n=0.5 p$ as $\left(X^{\prime} X\right)$ is singular and the inverse does not exist. For $n=p$ an exact fit would be obtained.

The proportion F-probabilities for small $n$ and $p$ values were much higher than of the bigger $n$ and $p$ values in the class ( $>0.05$ ). Thus, for bigger values of $n$ and $p$ numbers the full model were much better than the, of the small values. For a good (strictly significant) model the case must be higher than 10 . Thus $n>28$ or $p>7$ for $n=4 p$. The model is then significant at 0.01 level.

## Chapter 8

## SUMMARY

In practise, when one has many candidate variables as explanatory variables in multiple regression, there is always the possibility that variables that are important determinants of the response variable might be omitted from the model while unimportant variables might be included. Both types of errors are important, and in this paper we attempt to quantify the probabilities of these errors.

The forward model has been addressed to determine the error rate.
The mean-squared error is intimately related to prediction accuracy. The meansquared error for each $n$ versus $p$ case has an exponential downward trend as $n$ increase (or $p$ ) for both the full- and forward models for each of the $n$ versus $p$ groups. The full regression model can however not be done for the cases $n=0.5 p$ as ( $X^{\prime} X$ ) is singular and the inverse does not exist. For $n=p$ an exact fit would be obtained.

The mean-squared error of the forward model for the estimated $\boldsymbol{\beta}$, ( $\widehat{\boldsymbol{\beta}}$ ) form the true $\boldsymbol{\beta}$ is lower than that of the full model for the case where $n=2 p$ and more or less the same than the case where $n=4 p$. Looking at this, the forward regression model is a more accurate model than the full model in this case. In the case where $n=4 p$, both models are more or less the same as prediction accuracy.

A reduction of the full model in many cases is necessary, but reasons for these requirements are outside the scope of this dissertation. In many of the cases the forward selection is preferred over the full model.

The best forward selection analysis is found in the cases where $n=4 p$ and $n>36$. The probability of a correct classification will then be higher than $60 \%$.

For a multiple, linear forward regression analysis the lowest probability for the $x_{i}$ 's to be misclassified is within the classification of the $n=4 p$ group, especially for the cases higher than $16(\mathrm{n}>36)$. Each test was done nominally at $\alpha=0.05$, but the actual significance level seems to be between 0.08 and 0.12 depending on $n$ and $p$. This indicates that forward selection is a reliable method to use, but the significance level may have to be adjusted.

Forward regression in all the cases can be done but the accuracy of the model must be kept in mind.

If forward regression analysis is done in cases where $n=0.5 p$ it would be advisable that $\mathrm{n}>30$. (Thus is not tested in this dissertation). Forward regression must be used very wisely when $n=0.5 p$ or other analytical methods like the Lasso shrinkage method must preferably be used.

To conclude, the analysis of an accurate forward regression analysis can be regarded as reliable, provided the sample size is big enough ( $n \geq 4 p$ ).

## Chapter 9

## CONCLUTIONS AND RECOMMENDATIONS ABOUT FORWARD REGRESSION RECOMMENDATIONS FOR FURTHER STUDY

The analysis of an accurate forward regression analysis can be regarded as reliable, provided the sample size is big enough ( $n \geq 4 p$ ) and $p \geq 4$.

The best forward selection analysis is found in the cases where $n=4 p$ and $n>36$. The probability of a correct classification will then be higher than $60 \%$ in study.

This dissertation is only a guideline for using forward selection, keeping the accuracy of the models in mind where the cases are $n=0.5 p, p, 2 p$ and $4 p$ with an error $\sim N(0,4)$ and where x is normally distributed with

$$
\boldsymbol{\mu}_{\boldsymbol{x}}=\{\mathbf{0}\} \text { and } \boldsymbol{\Sigma}_{X}=\left(\begin{array}{ccc}
1 & \cdots & 0.5 \\
\vdots & \ddots & \vdots \\
0.5 & \cdots & 1
\end{array}\right)
$$

The dissertation could be built upon in a number of ways.
It is suggested that proper guidelines for statisticians and researchers must be published, given guidelines for using forward selection for all the normality conditions of $x$ and for the different noise levels.

It is shown that the different subset selection methods do not differ too much.
In a case where forward selection is not the appropriate method (for a chosen n and p ), better guidelines for using other analytical methods must be published.

To further clarify the properties of forward regression, the following additional simulations would be usefull:

- Other values of $\rho$, rather than 0.5
- Other proportions of variables with $\beta_{\mathrm{j}}=1$ and $\beta_{\mathrm{j}}=0$
- Cases where the irrelevant variables $\left(\beta_{\mathrm{j}}=0\right)$ are uncorrelated with the relevant variables $\left(\beta_{\mathrm{j}}=1\right)$
- Situations with serious multicollinearity
- Still larger values of $p$ (larger than 20)
- The non-zero regression coefficients $\beta_{\mathrm{j}}$ not all equal
- Stepwise regression may also be studied in a similar way.
