Fitting of survival functions for grouped data

on insurance policies

by

Elizabeth Magrietha Louw

Submitted in fulfilment of part of the requirements
for the degree of Doctor of Philosophiae
in the Faculty of Natural and Agricultural Sciences
University of Pretoria

Supervisor: Professor N.A.S. Crowther

January 2002
Preface

I am extremely grateful to my supervisor, Professor N.A.S. Crowther, for his careful supervision, positive guidance and constructive comments throughout.

I appreciated the enthusiastic encouragement of my family and friends. The patience and understanding and continuous support of my husband, Johann, and daughters, Hannelie and Annemarie, kept me going.

Chapter 1

INTRODUCTION

1.1 Background

Survival data consist of a response variable that measures the duration of time until a specified event occurs, and a set of covariates that can be either discrete or continuous. Some observations are right-censored, that is, the time until the event occurs, is not observed due to withdrawal or termination of the study. Thus survival data consist of a response variable (duration of time), as well as an additional variable indicating which responses are observed survival times and which are censored times and some covariates.

In this thesis, a structured framework for the analysis of policy survival times has been developed. Such a framework must be embedded in the experimental design. The lifetime of a policy is measured from the inception date up to the lapsing date or a cut-off point. If the lapsing date is prior to a cut-off point of the study, determined in advance, then the lifetime is observed (an uncensored observation). If a policy is still in force (alive) when the cut-off point is reached, the lifetime of this policy is said to be right-censored. This thesis focuses on grouped data for lifetimes. This scenario has become extremely important, not only for application in the actuarial context, but also in other fields.

In this thesis, the analysis takes account of the actual lifetime (duration) of the policy rather than just recording the fact that the policy lapsed or was still alive after (say) twelve months. In other words, the response variable, lifetime, is a continuous one, and the whole distribution of lifetimes can be used. This is in contrast to a categorical response where a
loglinear logit model can be used to express the relationship among the categorical response and some covariates at a fixed time point of twelve months, conditional on a restricted experimental design where all the policies must have an exposure of at least twelve months when investigating the lapses of policies in the first year. There is no such restrictions in the more general experimental design used in this thesis where all the policies can be used in the analysis, even those policies with inception dates very close to the cut-off point.

All the policies that are written during a certain month and are recorded at the end of that month as that month's business, can be considered as a group of policies with a common starting point or entry time. In this way policies written in different months or time-periods have different entry times. This is called staggered entry of policies.

The policy lifetimes (observed and censored lifetimes) are typically of a discrete nature and principles of grouped data have to be taken into account when fitting lifetime distributions to such survival data. Statistical analysing techniques for this kind of grouped data are currently insufficient.

1.2 The Research Problem

The aim of the research is the statistical modelling of parametric survival distributions of grouped survival data of long- and shortterm policies in the insurance industry, by means of a method of maximum likelihood estimation subject to constraints. The statistical methodology is developed from previous research on maximum likelihood estimation subject to constraints (refer to [11, 30]) and special attention is given to the staggered entry of policies and the fitting of parametric regression models.

Much literature exist on the fitting of survival distributions, mainly in connection with non-parametric analyses or the semi-parametric proportional hazards regression model of Cox [6, 23, 41]. Theoretical results for continuous data of lifetimes are well developed. Corresponding results for grouped data of lifetimes or the so-called interval-censored data are available only in special cases, and then again mainly in the non-parametric and semi-parametric case (refer to [33, 15, 14]). Only in recent years interval censoring in parametric model fitting were addressed by [27, 22, 14, 36]. This was made possible by modern computing power and sophisticated statistical programming languages.
The standard method of estimation to be used in the literature is to maximize the partial likelihood (at Cox's model) or the full likelihood (at parametric regression models). The estimates of the parameters are then found by maximizing the likelihood function numerically. The methodology of maximum likelihood estimation subject to constraints, used in this thesis, leads to explicit expressions for the estimates of the parameters, as well as for approximated variances and covariances of the estimates, which gives exact maximum likelihood estimates of the parameters. This makes direct extension to more complex designs feasible.

Once the parameters of the survival distributions have been estimated, estimated hazard and survivor functions, odds of a lapse, odds ratios and hazard ratios at time $t$ can be directly calculated, as well as estimated percentiles for the fitted survival distributions. These estimates form the statistical foundation for scientific decisionmaking with respect to actuarial design, maintenance and marketing of insurance policies.

The intrinsic value of the methodology described in this thesis is of fundamental importance to the actuarial science. The statistical modelling offers parametric models for survival distributions, in contrast with non-parametric models that are used commonly in the actuarial profession. This leads to more accurate estimation procedures. When the parametric models provide a good fit to data, they tend to give more precise estimates of the quantities of interest such as odds ratios, hazard ratios or median lifetimes. Estimates of these quantities will tend to have smaller standard errors than they would in the absence of distributional assumptions.

Data from the insurance industry are extensive data sets with very large sample sizes. The focus in this thesis will be on the estimation of lifetime distributions, based on a large sample of lifetimes of policies that are grouped into intervals of lifetimes. The variance-covariance matrix can be estimated as part of this maximum likelihood estimation procedure subject to constraints, but no meaningful interpretation can be given to the exceedance probability values that are associated with the very small standard errors of the parameter estimates due to the large sample size. Therefore discrepancy values will be used to evaluate the fitting of the lifetime distributions.
1.3 Generalization of the Statistical Procedures

One important aspect of the research field of survival analysis is the wide range of types of application. Although the methodology in this thesis is developed specifically for the insurance industry, it may be applied in the normal context of research and scientific decisionmaking, that includes for example survival distributions for the medical, biological, engineering, econometric and sociological sciences.

1.4 Future Research

The potential for extending the methodology to other realistic practical application is unlimited. This can be to the advance of the insurance industry in general. The models should reflect an interactive adaptability for direct application in practice by salesforce (the marketing people on ground level), as well as for actuarial planning.

1.5 Outlay of chapters

In chapter two, basic survival functions are defined and a description of the survival distributions that are used in this thesis, together with their properties, are given. The construction of different likelihood functions is also discussed.

In chapter three, parametric models are fitted to a single sample of survival data. The standard method of maximum likelihood estimation is reviewed. This is followed by the methodology of maximum likelihood estimation subject to constraints, applied in two different scenarios: a fixed censoring time as well as staggered entry of policies. The chapter is concluded with simulation studies to compare the estimates of the parameters obtained by the standard and the proposed estimating procedures.

In chapter four parametric regression models are fitted and important indicators of the effect of the covariates are defined such as risk scores (hazard ratios) and indices (odds ratios).

The developed theoretical results are applied in chapter five to a typical data set from an insurance company.
Chapter six concludes with a summary of the most important results in this thesis and focuses on application of these results in practice, especially in the actuarial industry.

All computer programs that were written in the SAS/IML language to perform the new methodology are given in appendix A.

The abstract appears at the end of the thesis, just after the references.
Chapter 2

SURVIVAL FUNCTIONS AND DISTRIBUTIONS

2.1 Introduction

The aim of this chapter is to introduce notation and survival concepts and to summarize properties of the survival distributions to be used in this thesis.

2.2 Notation

2.2.1 Right-censored continuous survival data

Let $X$ be a nonnegative continuous random variable denoting the lifetime (or survival time) of a policy. The lifetime of a policy is measured from inception date up to the lapsing date. If the lapsing date is prior to a fixed termination date of the study, determined in advance, then the lifetime is observed (an uncensored observation). If a policy is still in force (alive) when the termination point is reached, the lifetime of this policy is said to be right-censored.
A fixed censoring time

Consider the simplest scenario where all policies enter the study at the same time. Let \( C \) be the fixed termination date of the study, determined in advance. \( C \) is then the preassigned fixed censoring time. Instead of observing \( X_1, X_2, \ldots, X_n \), only \( T_1, T_2, \ldots, T_n \) are observed where

\[
T_j = \begin{cases} 
X_j & \text{if } X_j \leq C \\
C & \text{if } X_j > C
\end{cases}
\]

The survival data, based on a sample of size \( n \), can then be represented by pairs of random variables \((T_j, \delta_j)\) where \( T_1, T_2, \ldots, T_n \) are independent identically distributed random variables, each with distribution function \( F \) and density function \( f \). \( \delta_j \) is the survival status of the \( j \)th policy and indicates whether the lifetime for the \( j \)th policy corresponds to a lapse (\( \delta_j = 1 \)) or is censored (\( \delta_j = 0 \)). This type of censoring is known as Type I right-censoring.

Staggered entry of policies

Staggered entry of policies occur when policies enter the study at different times.

Define \( C_j \) as the potential censoring time for the \( j \)th policy, associated with lifetime \( X_j \). \( C_1, C_2, \ldots, C_n \) are independent identically distributed random variables, each with distribution function \( G \) and density function \( g \).

Only pairs \((T_1, \delta_1), (T_2, \delta_2), \ldots, (T_n, \delta_n)\) can be observed where

\[
T_j = \min(X_j, C_j) \text{ for the } j \text{th policy}
\]

\[
\delta_j = \begin{cases} 
1 & \text{if } X_j \leq C_j \text{, that is, } X_j \text{ is not censored} \\
0 & \text{if } X_j > C_j \text{, that is, } X_j \text{ is censored}
\end{cases}
\]

\( T_1, T_2, \ldots, T_n \) are independent identically distributed random variables with distribution function \( F \) if \( T_j = X_j \) and distribution function \( G \) if \( T_j = C_j \).

Random entries to the study are assumed. This type of censoring is known as random right-censoring. Type I right-censoring is a special case of the random censorship model by simply setting \( C_i = C \). With random censoring the crucial assumption that \( X_i \) and \( C_i \) are independent, is made. This assumption means that censoring is not related to any factors associated with the actual survival time. This is called non-informative censoring. A graphical test to examine the assumption of non-informative censoring is given by [5, page
2.2.2 Discrete data

Sometimes the lifetime $T$ is a discrete random variable. Discrete lifetimes arise due to rounding off time measurements. Lifetimes of policies are usually measured on a discrete time-scale (to the nearest month).

If the lifetimes of the policies are distinct and $t_1 < t_2 < \ldots < t_n$ denotes the ordered lifetimes, then $R(t_i)$ is the risk set at time $t_i$, that is the set of policies that are still alive at a time just prior to $t_i, i = 1, 2, \ldots, n$.

To allow for possible ties in the data, suppose that the lapses occur at $D$ distinct times $t_1 < t_2 < \ldots < t_D$. Define

\begin{align*}
    d_i &= \text{number of lapses at time } t_i \\
    Y_i &= \text{number of policies that are at risk at an instant just prior to time } t_i \\
         &= \text{number of policies that are still alive at time } t_i \text{ or lapse at time } t_i \\
         &= \text{number of policies in the risk set } R(t_i)
\end{align*}

2.2.3 Interval-censored data

Introduction

In the case where a large group of policies are followed from a common starting point (the inception date) over certain periods of time, the data consist of only the number of policies that lapse or are censored within various time-intervals. Interval censoring is used to describe this situation where a policy's lifetime is known only to lie between two values (interval boundaries). Interval-censored data can involve left and right censoring, as being outlaid in the scheme of [4, page 144-145].
Notation

Assume that the lifetime for the $j^{th}$ policy is bounded between two known values, denoted $b_j \leq T < c_j$ and it is known whether the policy lapsed. The intervals do not necessarily coincide and may be overlapping. Left- and right-censoring are special cases of interval-censored data. Denote the left-censoring time by $C_l$ and the right-censoring time by $C_r$. Observations that are left-censored have $b_j = 0$, $c_j = C_l$ and $\delta_j = 1$. Observations that are right-censored have $b_j = C_r$, $c_j = \infty$ and $\delta_j = 0$.

Grouped data

Grouped data arise due to the grouping of the continuous lifetimes of policies into $k$ adjacent, non-overlapping fixed intervals

$$I_j = [a_{j-1}; a_j) \quad j = 1, 2, ..., k$$

with $a_0 = 0$ and $a_k = \infty$.

Thus grouped data consist of the numbers of observed and censored lifetimes falling into each of the $k$ intervals. In the case of the last interval $I_k = [a_k; \infty)$ the policies will lapse some time in this open interval and all the lifetimes in this interval can be considered as observed.

Define

$$d_j = \text{number of policies that lapsed in } I_j$$

$$Y'_j = \text{number of policies entering interval } I_j \text{ that have not lapsed}$$

$$W_j = \text{number of policies with censored lifetimes in } I_j$$

assuming that censored lifetimes are independent of the time those policies would have had they been observed until the lapse

$$Y_j = Y'_j - \frac{W_j}{2}$$

= number of policies at risk of lapsing in $I_j$ (policies that are still alive at $a_{j-1}$)

assuming that censored and observed lifetimes are uniformly distributed over the interval
2.3 Basic Survival Functions

2.3.1 Introduction

Four functions characterize the distribution of \( T \), namely the **survivor function**, which is the probability of a policy surviving beyond time \( t \), the **hazard rate function** which is the chance a policy, surviving up to time \( t \), will lapse in the next instant, the **probability density (or mass) function** which is the unconditional probability of a lapse at time \( t \), and the **mean residual life** at time \( t \), which is the mean time to a lapse, given no lapse at \( t \). If any one of these four functions is known, the other three then can be uniquely determined.

2.3.2 Probability distribution and distribution function

For a **continuous** random variable \( T \) the probability density function of \( T \) is

\[
f(t) = \lim_{dt \to 0} \frac{P(t < T < t + dt)}{dt} = \lim_{dt \to 0} \frac{F(t + dt) - F(t)}{dt} \quad (2.3.1)
\]

with cumulative distribution function

\[
F(t) = P(T \leq t) = \int_0^t f(x) \, dx \quad (2.3.2)
\]

\( f(t) \) is the unconditional probability of a lapse at time \( t \) (probability per unit of time over a small interval of time) and is called the unconditional lapse rate.

For a **discrete** random variable \( T \) the probability mass function of \( T \) at time \( t_i \) is

\[
p(t_i) = \begin{cases} 
  P(T = t_i) & i = 1, 2, \ldots \\
  0 & \text{elsewhere} 
\end{cases} \quad (2.3.3)
\]

The distribution of \( T \) is characterized by either one of two equivalent functions, namely the **survivor function** and the **hazard rate function**.
2.3.3 **Survivor function**

The survivor function at time \( t \) is the probability of a policy surviving beyond time \( t \), also called the survival rate at time \( t \).

The survivor function for **continuous** \( T \) is defined as

\[
S(t) = P(T > t) = \int_t^\infty f(x) \, dx = 1 - F(t) \quad \text{for} \quad t > 0 \quad (2.3.4)
\]

- The graph of \( S(t) \) versus \( t \) is called the survival curve
- \( S(t) \) is a continuous, strictly decreasing function with \( S(0) = 1 \) and \( S(\infty) = 0 \)
- \( f(t) = -\frac{d}{dt} S(t) \)

The survivor function for **discrete** \( T \) is defined as

\[
S(t) = P(T > t) = \sum_{t_j > t} p(t_j) \quad \text{for} \quad t > 0 \quad (2.3.5)
\]

- The graph of \( S(t) \) versus \( t \) is for discrete \( T \) a nonincreasing step function with jumps downward at \( t_1, t_2, \ldots \)

2.3.4 **Hazard rate function**

The hazard rate function at time \( t \) is the **conditional** probability of a lapse in the next instant just beyond time \( t \) **given that the policy has survived up to time** \( t \). This is also called the instantaneous lapse rate assuming that the policy was alive up to time \( t \).

For a **continuous** random variable \( T \) the hazard rate function at time \( t \) is defined as
Survival Functions and Distributions

\[ h(t) = \lim_{dt \to 0} \frac{P(t < T < t + dt \mid T > t)}{dt} \]
\[ = \lim_{dt \to 0} \frac{P[(t < T < t + dt) \cap (T > t)]}{P(T > t)dt} \]
\[ = \lim_{dt \to 0} \frac{P(t < T < t + dt)}{dt} \cdot \frac{1}{P(T > t)} \]
\[ = f(t) \cdot \frac{1}{S(t)} \]

\[ \Rightarrow h(t) = \frac{f(t)}{S(t)} = -\frac{\frac{d}{dt}S(t)}{S(t)} \]

(2.3.6)

For a discrete random variable \( T \) the hazard rate function at time \( t_j \) is defined as

\[ h(t_j) = P(T = t_j \mid T \geq t_j) = \frac{P[(T = t_j) \cap (T \geq t_j)]}{P(T \geq t_j)} \]
\[ = \frac{P(T = t_j)}{P(T > t_{j-1})} = \frac{p(t_j)}{S(t_{j-1})} \]
\[ = \frac{S(t_{j-1}) - S(t_j)}{S(t_{j-1})} = 1 - \frac{S(t_j)}{S(t_{j-1})} \]

\[ \Rightarrow \frac{S(t_j)}{S(t_{j-1})} = 1 - h(t_j) \]

Note that \( S(t) = \frac{S(t_1)}{S(t_0)} \cdot \frac{S(t_2)}{S(t_1)} \cdot \ldots \cdot \frac{S(t)}{S(t_{j-1})} \)

\[ \Rightarrow S(t) = \prod_{t_j \leq t} \frac{S(t_j)}{S(t_{j-1})} = \prod_{t_j \leq t} [1 - h(t_j)] \]

(2.3.7)

The hazard rate is zero for a discrete random variable \( T \) except at points where a lapse could occur.
2.3.5 Cumulative hazard function

For continuous $T$ the cumulative hazard function is defined as

$$H(t) = \int_0^t h(x) \, dx$$

$$= \int_0^t -\frac{d}{dx} S(x) \, dx$$

$$= -[\ln S(t) - \ln S(0)]$$

$$= -\ln S(t)$$

$$\Rightarrow h(t) = \frac{d}{dt} H(t) = -\frac{d}{dt} \ln S(t) \quad (2.3.8)$$

For discrete $T$ the cumulative hazard function is defined as

$$H(t) = \sum_{t_j \leq t} h(t_j)$$

2.3.6 Median lifetime, mean lifetime and mean residual lifetime

The survivor function is used to determine the median lifetime (median time to a lapse) and other percentiles.

$$\text{median } t_{50} = \text{ time point at which } S(t_{50}) \leq 0.5 \quad (2.3.9)$$

$$p^{th} \text{ percentile } = t_p \text{ so that } S(t_p) = \frac{100 - p}{100} \quad (2.3.10)$$

The mean lifetime is represented as the area under the survival curve.

$$\mu = E(T) = \int_0^\infty S(t) \, dt \quad (2.3.11)$$

The variance of $T$ is related to the survivor function by

$$\text{var}(T) = 2 \int_0^\infty tS(t) \, dt - \left[ \int_0^\infty S(t) \, dt \right]^2 \quad (2.3.12)$$
The mean residual lifetime (mean amount of lifetime remaining after a particular time \(t\)) is defined as

\[
mrl(t) = E(T - t \mid T > t) = \frac{\int_{t}^{\infty} (x-t) f(x) \, dx}{P(T > t)} = \frac{\int_{t}^{\infty} S(x) \, dx}{S(t)}
\]  

(2.3.13)

2.4 Survival Models

2.4.1 Introduction

In this section analytical forms of survival distributions that are often used in fitting survival data are given. Properties of the Weibull survival model are discussed by [2, 25, 26], while [22] describes the log-logistic survival model and [34, 26] the lognormal survival model.

2.4.2 Weibull distribution

Consider \(T \sim \text{Weib}(\lambda, \alpha)\)

\[
\begin{align*}
\lambda &= \text{scale parameter} \quad \lambda > 0 \\
\alpha &= \text{shape parameter} \quad \alpha > 0
\end{align*}
\]

- density function \(f(t) = \lambda \alpha t^{\alpha-1} \exp\{-\lambda t^\alpha\} \quad t > 0\)  
  (2.4.1)
- expected value \(E(T) = \Gamma(1 + \frac{1}{\alpha}) \cdot \lambda^{-\frac{1}{\alpha}}\)  
  (2.4.2)
- variance \(\text{var}(T) = \left[\Gamma(1 + \frac{2}{\alpha}) - \Gamma^2(1 + \frac{1}{\alpha})\right] \cdot \lambda^{-\frac{2}{\alpha}}\)  
  (2.4.3)
- survivor function \(S(t) = \exp(-\lambda t^\alpha)\)  
  (2.4.4)
- hazard function \(h(t) = \lambda \alpha t^{\alpha-1}\)  
  (2.4.5)
- \(p^{th}\) percentile \(t_p = \left[\frac{1}{\lambda} \ln\left(\frac{100}{100 - p}\right)\right]^\frac{1}{\alpha} \quad p = 1, 2, ..., 99\)  
  (2.4.6)
- \(\Rightarrow\) median lifetime \(t_{50} = \left[\frac{1}{\lambda} \ln\left(\frac{100}{100 - 50}\right)\right]^\frac{1}{\alpha}\)  
  \(= \left[\frac{1}{\lambda} \ln(2)\right]^\frac{1}{\alpha}\)  
  (2.4.7)
Note that

\[-\ln S(t) = \lambda t^\alpha\]

\[\Rightarrow \ln(-\ln S(t)) = \ln \lambda + \alpha \ln t\]  \hspace{1cm} (2.4.8)

2.4.3 The log-logistic distribution

Consider \( T \sim \text{log-logistic}(\lambda, \alpha) \)

\[\lambda = \text{scale parameter } \quad \lambda > 0\]
\[\alpha = \text{shape parameter } \quad \alpha > 0\]

Density function

\[f(t) = \frac{\lambda \alpha t^{\alpha-1}}{(1 + \lambda t^\alpha)^2} \quad \text{with } t > 0\]  \hspace{1cm} (2.4.9)

Expected value

\[E(T) = \frac{\pi \csc \frac{\pi}{\alpha}}{\alpha \lambda^{\frac{1}{\alpha}}} \quad \text{if } \alpha > 1\]  \hspace{1cm} (2.4.10)

Variance

\[\text{var}(T) = \frac{2\pi \csc \frac{2\pi}{\alpha}}{\alpha \lambda^{\frac{2}{\alpha}}} - E(T^2) \quad \text{if } \alpha > 2(2.4.11)\]

Survivor function

\[S(t) = (1 + \lambda t^\alpha)^{-1}\]  \hspace{1cm} (2.4.12)

Hazard function

\[h(t) = \frac{\lambda \alpha t^{\alpha-1}}{(1 + \lambda t^\alpha)}\]  \hspace{1cm} (2.4.13)

Odds of a lapse at time \( t \)

\[\frac{1 - S(t)}{S(t)} = \lambda t^\alpha\]  \hspace{1cm} (2.4.14)

\( p^{th} \) percentile

\[t_p = \left[ \frac{1}{\lambda} \cdot \frac{p}{100 - p} \right]^{\frac{1}{\alpha}}\]  \hspace{1cm} (2.4.15)

\[\Rightarrow \text{median lifetime } \quad t_{50} = \left( \frac{1}{\lambda} \right)^{\frac{1}{\alpha}}\]  \hspace{1cm} (2.4.16)

Note that

\[\ln \left( \frac{1 - S(t)}{S(t)} \right) = \ln \lambda + \alpha \ln t\]  \hspace{1cm} (2.4.17)

2.4.4 The lognormal distribution

Consider \( T \sim \text{lognormal}(\mu, \sigma^2) \).

Density function

\[f(t) = \frac{1}{t\sigma(2\pi)^{\frac{1}{2}}} \exp \left\{ -\frac{1}{2} \left( \frac{\ln(t) - \mu}{\sigma} \right)^2 \right\} \quad \text{with } t > 0\]  \hspace{1cm} (2.4.18)
Survival Functions and Distributions

\begin{align*}
\text{expected value} \quad E(T) &= \exp(\mu + 0.5\sigma^2) \\
\text{variance} \quad \text{var}(T) &= \exp(2\mu + \sigma^2) \cdot [\exp(\sigma^2) - 1] \\
\text{survivor function} \quad S(t) &= 1 - \Phi \left[ \frac{\ln(t) - \mu}{\sigma} \right] \\
&\quad \text{with } \Phi \text{ the standard normal distribution function} \\
\text{hazard function} \quad h(t) &= f(t)/S(t) \\
\text{$p^{th}$ percentile} \quad t_p &= \exp(\mu + \sigma z_p) \\
&\quad \text{with } z_p \text{ the } p^{th} \text{ percentile of the n(0,1) distribution.}
\end{align*}

2.4.5 Location-scale parameter survival models

Introduction

A univariate location-scale parameter distribution is described by [13] as a distribution with a probability density function of the form

\[ f(y; \mu, \sigma) = \frac{1}{\sigma} \cdot g\left(\frac{y - \mu}{\sigma}\right) \quad -\infty < y < \infty \]  

where

\begin{align*}
\mu &= \text{location parameter} \quad -\infty < \mu < \infty \\
\sigma &= \text{scale parameter} \quad \sigma > 0 \\
g &= \text{a fully specified probability density function defined on } (-\infty, \infty)
\end{align*}

The survivor function corresponding to Equation 2.4 .23 is

\[ G\left[\frac{y - \mu}{\sigma}\right] \quad \text{where } \quad G(x) = \int_x^\infty g(z) \, dz \]  

The extreme value, logistic and normal distributions are examples of location-scale parameter distributions that are used in fitting survival models to survival data.

The extreme value distribution

Consider $Y \sim \text{EV}(\sigma, \mu)$ \quad $\mu = \text{location parameter}$ \quad $\sigma = \text{scale parameter} \quad \sigma > 0$
density function \[ f(y) = \frac{1}{\sigma} \cdot \exp \left\{ \left( \frac{y - \mu}{\sigma} \right) - \exp \left( \frac{y - \mu}{\sigma} \right) \right\} \quad -\infty < y < \infty \] (2.4 .25)

expected value \[ E(Y) = \mu - 0.5772 \sigma \quad \text{Euler's constant} = 0.5772 \] (2.4 .26)

variance \[ var(Y) = \frac{\pi^2 \sigma^2}{6} \] (2.4 .27)

The extreme value distribution with \( \mu = 0 \) and \( \sigma = 1 \) is termed the standard extreme value distribution. A discussion of the extreme value distribution is given by [34].

The logistic distribution

Consider \( Y \sim \text{logistic}(\mu, \sigma) \)

\[ \mu = \text{location parameter} \quad \sigma = \text{scale parameter} \quad \sigma > 0 \]

density function \[ f(y) = \frac{1}{\sigma} \cdot \frac{\exp \left( \frac{y - \mu}{\sigma} \right)}{\left\{ 1 + \exp \left( \frac{y - \mu}{\sigma} \right) \right\}^2} \quad -\infty < y < \infty \] (2.4 .28)

expected value \[ E(Y) = \mu \] (2.4 .29)

variance \[ var(Y) = \frac{\pi^2 \sigma^2}{3} \] (2.4 .30)

The logistic distribution is a symmetrical distribution whose probability density function is very similar to that of the normal distribution.

The logistic distribution with \( \mu = 0 \) and \( \sigma = 1 \) is termed the standard logistic distribution.

The properties of the logistic distribution are discussed by [2].

The normal distribution

Consider \( Y \sim \text{normal}(\mu, \sigma) \)

\[ \mu = \text{location parameter} \quad \sigma = \text{scale parameter} \quad \sigma > 0 \]
density function \[ f(y) = \frac{1}{\sigma(2\pi)^{\frac{1}{2}}} \cdot \exp \left\{ -\frac{1}{2} \left( \frac{y - \mu}{\sigma} \right)^2 \right\} \quad -\infty < y < \infty \] (2.4.31)

expected value \[ E(Y) = \mu \] (2.4.32)

variance \[ \text{var}(Y) = \sigma^2 \] (2.4.33)

The normal distribution with \( \mu = 0 \) and \( \sigma = 1 \) is termed the standard normal distribution.

### 2.5 Relationships between Survival Distributions

#### 2.5.1 Introduction

In analyzing survival data it is often convenient to work with \( Y = \ln(T) \), the logarithm of the lifetimes.

#### 2.5.2 Relationship between the Weibull and extreme value distributions

The extreme value distribution arises when lifetimes are taken to be Weibull distributed. The following relationship between the Weibull and extreme value distributions exists:

\[ T \sim \text{Weib}(\lambda, \alpha) \iff Y = \ln(T) \sim \text{EV} \left( \frac{1}{\alpha}, \frac{-\ln\lambda}{\alpha} \right) \] (2.5.1)

This result can be proved in the following way. If \( T \sim \text{Weib}(\lambda, \alpha) \) with density function

\[ f_T(t) = \lambda \alpha t^{\alpha-1} \exp\{ -\lambda t^\alpha \} \quad t > 0 \]

and survivor function \( S_T(t) = \exp\{ -\lambda t^\alpha \} \)

then, by using the transformation technique, \( Y = \ln(T) \) has density function

\[ f_Y(y) = f_T(t) \cdot \left| \frac{dt}{dy} \right| = \lambda \alpha (e^y)^{\alpha-1} \exp\{ -\lambda (e^y)^\alpha \} \cdot | e^y | \]
\[ S_Y(y) = \exp\{-\lambda e^{\alpha y}\}. \quad (2.5.4) \]

Equation 2.5.2 implies that
\[
f_Y(y) = \frac{\lambda \alpha \exp\{\alpha y - \lambda e^{\alpha y}\}}{\exp\{\ln(\lambda)\} \cdot \alpha \cdot \exp\{\alpha y - \exp\{\ln(\lambda)\}\exp\{\alpha y\}\}}
\]
\[
= \frac{\alpha \exp\{\alpha y + \ln(\lambda) - \exp\{\alpha y + \ln(\lambda)\}\}}{\exp\left\{\alpha \left[ y - \frac{-\ln(\lambda)}{\alpha}\right]\right\} - \exp\left\{\alpha \left[ y - \frac{-\ln(\lambda)}{\alpha}\right]\right\}}. \quad (2.5.5)
\]

Let \( \mu = \frac{-\ln(\lambda)}{\alpha} \) and \( \sigma = \frac{1}{\alpha} \) in Equation 2.5.5.
\[
\Rightarrow f_Y(y) = \frac{1}{\sigma} \exp\left\{\frac{y - \mu}{\sigma} - \exp\left\{\frac{y - \mu}{\sigma}\right\}\right\}. \quad (2.5.6)
\]

Equation 2.5.6 is the density of the extreme value distribution with parameters \( \sigma \) and \( \mu \)
\[
\Rightarrow Y \sim EV(\sigma, \mu) \equiv EV\left(\frac{1}{\alpha}, \frac{-\ln(\lambda)}{\alpha}\right). \quad (2.5.7)
\]

This leads to the relationship between the Weibull distribution and the extreme value distribution:
\[
T \sim \text{Weib}(\lambda, \alpha) \iff Y - \ln(T) \sim EV\left(\frac{1}{\alpha}, \frac{-\ln(\lambda)}{\alpha}\right) \quad (2.5.8)
\]

2.5.3 Relationship between the log-logistic and logistic distributions

The log-logistic distribution is related to the logistic distribution by the relationship
\[
T \sim \log\text{-logistic}(\lambda, \alpha) \iff Y = \ln(T) \sim \text{logistic}(\ln\lambda, \frac{1}{\alpha}). \quad (2.5.9)
\]
2.5.4 Relationship between the lognormal and normal distributions

The lognormal distribution is related to the normal distribution by the relationship

\[ T \sim \text{lognormal}(\mu, \sigma^2) \iff Y = \ln(T) \sim \text{normal}(\mu, \sigma^2). \] \hspace{1cm} (2.5.10)

In view of the similarity of the normal and logistic distributions, the lognormal model will tend to be very similar to the loglogistic model.

2.5.5 A linear model representation in log-time

Consider the following log-linear model that describes the basic underlying distribution of lifetimes:

\[ Y = \ln T = \mu + \sigma W \]

where \( W \) is the error distribution, \( \mu \) is the location parameter and \( \sigma \) is the scale parameter. A variety of distributions for \( W \) can be assumed, for example the standard extreme value distribution, the standard logistic distribution or the standard normal distribution.

- If this linear model format \( Y = \ln T = \mu + \sigma W \) is used where \( W \) has the standard extreme value distribution, that is \( W \sim EV(1,0) \), with density

\[ f(w) = \exp\{w - \exp(w)\} \quad -\infty < w < \infty \]

then \( Y = \ln(T) \) has an extreme value \( EV\left(\frac{1}{\alpha}, -\frac{\ln \lambda}{\alpha}\right) \) distribution and \( T \) has an underlying Weibull\((\lambda, \alpha)\) distribution with parameters

\[ \lambda = \exp\left\{\frac{-\mu}{\sigma}\right\} \quad \text{and} \quad \alpha = \frac{1}{\sigma}. \] \hspace{1cm} (2.5.11)

- If this linear model format \( Y = \ln T = \mu + \sigma W \) is used where \( W \) has the standard logistic distribution with density

\[ f(w) = \frac{\exp(w)}{(1 + \exp(w))^2} \quad -\infty < w < \infty \]

then \( Y = \ln(T) \) has a logistic\(\left(\frac{1}{\alpha}, -\frac{\ln \lambda}{\alpha}\right)\) distribution and \( T \) has an underlying log-logistic\((\lambda, \alpha)\) distribution also with parameters

\[ \lambda = \exp\left\{\frac{-\mu}{\sigma}\right\} \quad \text{and} \quad \alpha = \frac{1}{\sigma}. \] \hspace{1cm} (2.5.12)
• If this linear model format $Y = \ln T = \mu + \sigma W$ is used where $W$ has the standard normal distribution with density

$$f(w) = \frac{\exp(w^2)}{(2\pi)^{\frac{1}{2}}} \quad -\infty < w < \infty$$

then $Y = \ln(T)$ has a normal($\mu, \sigma^2$) distribution and $T$ has an underlying lognormal($\mu, \sigma^2$) distribution.

The first of the three results is now proven. The other two results follow in a similar way.

If the error distribution $W \sim EV(1, 0)$, with density

$$f(w) = \exp\{w - \exp(w)\} \quad -\infty < w < \infty$$

then, by using the transformation technique and the fact that $W = \frac{\ln(T) - \mu}{\sigma}$, the density function of $T$ is

$$f_T(t) = f_W(w) \cdot \left| \frac{dw}{dt} \right|$$

$$= \exp\left\{\frac{\ln(t) - \mu}{\sigma} - \exp\left\{\frac{\ln(t) - \mu}{\sigma}\right\}\right\} \cdot \left| \frac{1}{\sigma t} \right|$$

$$= \exp\left\{\frac{1}{\sigma} \ln(t) - \frac{\mu}{\sigma} - \exp\left\{\frac{\ln(t) - \mu}{\sigma}\right\}\right\} \cdot \left| \frac{1}{\sigma t} \right|$$

$$= t^{\frac{1}{\sigma}} \cdot t^{-1} \cdot \frac{1}{\sigma} \cdot \exp\left\{-\frac{\mu}{\sigma}\right\} \cdot \exp\left\{-t^{\frac{1}{\sigma}} \cdot \exp\left\{-\frac{\mu}{\sigma}\right\}\right\}$$

$$= \exp\left\{-\frac{\mu}{\sigma}\right\} \cdot \frac{1}{\sigma} \cdot t^{\frac{1}{\sigma}-1} \cdot \exp\left\{-\exp\left\{-\frac{\mu}{\sigma}\right\} \cdot t^{\frac{1}{\sigma}}\right\}$$

$$= \exp\left\{-\frac{\mu}{\sigma}\right\} \cdot \frac{1}{\sigma} \cdot t^{\frac{1}{\sigma}-1} \cdot \exp\left\{-\exp\left\{-\frac{\mu}{\sigma}\right\} \cdot t^{\frac{1}{\sigma}}\right\}$$

Equation 2.5.13 is the density of the **Weibull distribution** with parameters

$$\lambda = \exp\left\{-\frac{\mu}{\sigma}\right\} \quad \text{and} \quad \alpha = \frac{1}{\sigma}$$

$$\Rightarrow T \sim \text{Weibull}(\lambda, \alpha)$$

In a similar way, if $W \sim EV(1, 0)$, with density

$$f(w) = \exp\{w - \exp w\} \quad -\infty < w < \infty$$

then, by using the transformation technique and the fact that $W = \frac{Y - \mu}{\sigma}$, the density function of $Y$ is

$$f_Y(y) = f_W(w) \cdot \left| \frac{dw}{dy} \right|$$

$$= \exp\left\{\frac{y - \mu}{\sigma} - \exp\left\{\frac{y - \mu}{\sigma}\right\}\right\} \cdot \left| \frac{1}{\sigma} \right|$$

$$= \frac{1}{\sigma} \cdot \exp\left\{\frac{y - \mu}{\sigma} - \exp\left\{\frac{y - \mu}{\sigma}\right\}\right\}$$

$$-\infty < y < \infty$$

(2.5.14)
Equation 2.5.14 is the density of the **extreme value distribution** with parameters \( \sigma \) and \( \mu \)

\[
Y \sim \text{EV}(\sigma, \mu) \equiv \text{EV} \left( \frac{1}{\alpha}, \frac{-\ln(\lambda)}{\alpha} \right)
\]

To summarize, if the general linear model format \( Y = \ln T = \mu + \sigma W \) is used, where the error distribution \( W \) is the standard extreme value \( \text{EV}(1, 0) \) distribution, then \( Y = \ln(T) \) has an extreme value \( \text{EV} \left( \frac{1}{\alpha}, \frac{-\ln \lambda}{\alpha} \right) \) distribution and \( T \) has an underlying \( \text{Weibull}(\lambda, \alpha) \) distribution with parameters

\[
\lambda = \exp \left\{ \frac{-\mu}{\sigma} \right\} \quad \text{and} \quad \alpha = \frac{1}{\sigma}.
\]

### 2.6 Construction of Likelihood Functions

#### 2.6.1 Introduction

The standard method of fitting survival models, specified in section 2.4, to survival data is the method of Maximum Likelihood Estimation (MLE). The first step is to create the specific likelihood function to be maximized. Likelihoods for different scenarios are now given.

#### 2.6.2 Likelihood function for random right-censored continuous data

Assume the random right-censoring model where \( T_1, T_2, \ldots, T_n \) are independent identically distributed random variables, each with distribution function \( F \) and density function \( f \). \( \delta_j \) is the survival status of the \( j^{th} \) policy and indicates whether the lifetime for the \( j^{th} \) policy corresponds to a lapse (\( \delta_j = 1 \)) or is censored (\( \delta_j = 0 \)).

Consider the pair \((T_i, \delta_i)\) for the \( i^{th} \) policy. The likelihood function is constructed by considering the contribution to the likelihood of the pairs \((t_i, \delta_i = 1)\) and \((t_i, \delta_i = 0)\) separately (refer to [25]).

- The contribution to the likelihood of the pair \((t_i, \delta_i = 1)\) is the probability that the \( i^{th} \) policy lapses at time \( t_i = x_i \). This probability is

\[
P(t_i \in (t_i, t_i + dt_i), \delta_i = 1) = P(T_i \in (t_i, t_i + dt_i), C_i > t_i)
= P(t_i < T_i < t_i + dt_i) \cdot P(C_i > t_i) \quad (2.6.1)
\]
\[ = f(t_i)dt_i \cdot [1 - G(t_i)] \quad (2.6.2) \]

Equation 2.6.1 follows from the fact that the observed survival times are independent of the censoring times.

- The contribution to the likelihood of the pair \((t_i, \delta_i = 0)\) is the probability that the \(i^{th}\) policy survives at least time \(t_i = C_i\). This probability is

\[
P(C_i \in (t_i, t_i + dt_i), \delta_i = 0) = P(C_i \in (t_i, t_i + dt_i), X_i > t_i) = P(t_i < C_i < t_i + dt_i) \cdot P(X_i > t_i) = g(t_i)dt_i \cdot S(t_i) \quad (2.6.3)
\]

The complete likelihood for the \(i^{th}\) policy under random censoring is

\[
L(t_i, \delta_i) = \{f(t_i)dt_i[1 - G(t_i)]\}^{\delta_i} \cdot \{g(t_i)dt_iS(t_i)\}^{1-\delta_i} \quad (2.6.4)
\]

Under the assumption of \(n\) independent censored and observed survival times, the full likelihood function is obtained by multiplying the respective contributions of the \(n\) pairs \((t_i, \delta_i)\) \(i = 1, 2, ..., n\) in the data set. This likelihood function of the full sample is

\[
L(t_1, t_2, ..., t_n; \delta_1, \delta_2, ..., \delta_n) = \prod_{i=1}^{n} L(t_i, \delta_i) = \prod_{i=1}^{n} \{f(t_i)dt_i[1 - G(t_i)]\}^{\delta_i} \cdot \{g(t_i)dt_iS(t_i)\}^{1-\delta_i} = \prod_{i=1}^{n} \left\{f(t_i)dt_i^{\delta_i} [S(t_i)]^{1-\delta_i}\right\} \cdot \left\{[1 - G(t_i)]^{\delta_i} [g(t_i)dt_i]^{1-\delta_i}\right\} \quad (2.6.5)
\]

Let \(\theta\) be the vector of parameters of the survival model. The survival model specifies the distribution of \(T_i\), independent from the distribution of \(C_i\). Only the first term of the product in Equation 2.6.5 involves the unknown lifetime parameters \(\theta\), so that the last term of the product, namely

\[
\left\{[1 - G(t_i)]^{\delta_i} [g(t_i)dt_i]^{1-\delta_i}\right\}
\]

can be treated like constants when maximizing \(L(t_1, t_2, ..., t_n; \delta_1, \delta_2, ..., \delta_n)\). Thus the likelihood function, up to a multiple constant, is

\[
L(\theta) = \prod_{i=1}^{n} \left\{f(t_i)\right\}^{\delta_i} \cdot \left\{S(t_i)\right\}^{1-\delta_i} \quad (2.6.6)
\]

The log-likelihood function

\[
\ln L(\theta) = \sum_{i=1}^{n} \delta_i \cdot \ln[f(t_i)] + \sum_{i=1}^{n} (1 - \delta_i) \cdot \ln[S(t_i)] \quad (2.6.7)
\]
is maximized to obtain the maximum likelihood estimators of the unknown parameters $\theta$. The procedure to obtain the values of the MLE involves taking derivatives of $\ln L(\theta)$ with respect to $\theta$, setting these equations equal to zero, and solving for $\theta$.

2.6.3 Likelihood function for interval-censored data

Consider the lifetime of the $j^{th}$ policy that is bounded between two known values, that is $b_j \leq T_j < c_j$. It is also known whether this policy lapsed. Observations that are left-censored have $b_j = 0$, $c_j = C_l$ and $\delta_j = 1$, while observations that are right-censored have $b_j = C_r$, $c_j = \infty$ and $\delta_j = 0$, with $C_l$ and $C_r$ the left- and right-censoring times respectively.

In constructing a likelihood function for interval-censored data, the information each observation provides, needs to be considered as the contribution of that observation to the likelihood (refer to [4]).

- An observation corresponding to an exact lifetime $t_i$ provides information on the probability that the lapse occurs at this time $t_i$, which is approximately equal to the density function of $T$ at this time. This probability is $f(t_i)$.

- For a right-censored observation, it is known that the lifetime is larger than $C_r$ with $C_r$ the right-censoring time. Thus the information provided is the survival function evaluated at $C_r$, that is $S(C_r)$.

- For a left-censored observation, it is known that the lapse has already occurred, so the contribution to the likelihood is the cumulative distribution function evaluated at $C_l$, that is $F(C_l) = 1 - S(C_l)$ with $C_l$ the left-censoring time.

- For interval-censored data, it is known that the lapse occurred within the interval, so that the information is the probability that the lifetime is in this interval. This probability is $S(b_i) - S(c_i)$.

The likelihood function may be constructed by putting together the above-mentioned components.

$$L(\theta) \propto \prod_{i \in D} f(t_i) \cdot \prod_{i \in RC} S(C_r) \cdot \prod_{i \in LC} [1 - S(C_l)] \cdot \prod_{i \in I} [S(b_i) - S(c_i)] \quad (2.6.8)$$

where
\( D \) is the set of observed lifetimes (lapses)  
\( RC \) is the set of right-censored observations  
\( LC \) is the set of left-censored observations  
\( I \) is the set of interval-censored observations

Consider the \( n \) pairs \((t_i, \delta_i)\) \( i = 1, 2, \ldots, n \) in the data set. Some of the responses are observed, while other responses are left, right or interval-censored. By making use of the principles of construction of the likelihood for interval-censored data in Equation 2.6 .8 it follows that

\[
L(\theta) = \prod_{i=1}^{n} \left[ f(t_i) \right]^{\delta_i} \cdot \left[ S(t_i) \right]^{1-\delta_i} \cdot \left[ 1 - S(t_i) \right]^{\delta_i} \cdot \left[ S(b_i) - S(t_i) \right]^{1-\delta_i} \tag{2.6 .9}
\]

with \( b_i \) the lower end of a censoring interval.

2.6.4 Likelihood function for right-censored grouped data

Consider the grouped data case as a special case of interval-censored data where the \( n \) lifetimes of policies are grouped into \( k \) adjacent, non-overlapping fixed intervals

\[ I_j = [a_{j-1}; a_j) \quad j = 1, 2, \ldots, k \]

with \( a_0 = 0 \) and \( a_k = \infty \).

The likelihood function for right-censored grouped data is stated by [24].

For complete data with no censored lifetimes, the \( n \) observed lifetimes are grouped into \( k \) intervals so that \( n = d_1 + d_2 + \ldots + d_k \) with \( d_j \) = number of lapses in \( I_j \).

The unconditional probability of a lapse in \( I_j \) is

\[ \pi_j = S(a_{j-1}) - S(a_j) \quad j = 1, 2, \ldots, k \]

Then \((d_1, d_2, \ldots, d_k)\) has a multinomial probability function

\[
\frac{n!}{d_1!d_2!\ldots d_k!} \pi_1^{d_1} \pi_2^{d_2} \ldots \pi_k^{d_k}
\]

The likelihood function can thus be taken as

\[
L(\theta) = n! \prod_{j=1}^{k} \left\{ \frac{[S(a_{j-1}) - S(a_j)]^{d_j}}{d_j!} \right\} \tag{2.6 .10}
\]
For **incomplete data**, where the $n$ censored and observed lifetimes are grouped into $k$ intervals, it is further assumed that the $W_j$ censored lifetimes in $I_j$ occur at the midpoint of the interval $a^*_j = a_{j-1} + \frac{1}{2} h_j$ with $h_j = a_j - a_{j-1}$ the length of interval $I_j$.

For interval $I_j = [a_{j-1}; a_j)$, **conditional** on surviving till $a_{j-1}$,

- the probability of a lapse is
  $$ q_j = \frac{S(a_{j-1}) - S(a_j)}{S(a_{j-1})} $$

- the probability of surviving until $a^*_j$ is
  $$ p^*_j = \frac{S(a_{j-1}) - S(a^*_j)}{S(a_{j-1})} $$

- the probability of surviving the full interval $I_j$ is
  $$ p_j = 1 - q_j = 1 - \frac{S(a_{j-1}) - S(a_j)}{S(a_{j-1})} = \frac{S(a_j)}{S(a_{j-1})} $$

The **conditional** likelihood for interval $I_j$ is

$$ L_j(\theta) \propto [q_j]^{d_j} \cdot [p^*_j]^{W_j} \cdot [p_j]^{Y_j - d_j - W_j} \quad (2.6.11) $$

where $Y_j$ is the number of policies at risk of lapsing in $I_j$, that is policies that are still alive at $a_{j-1}$.

The overall likelihood function is

$$ L(\theta) = \prod_{j=1}^{k} L_j(\theta) \quad (2.6.12) $$

If class intervals are narrow, another possibility is to treat the data as continuous and assume that all lifetimes in interval $I_j$ occur at the interval midpoint.
Chapter 3

PARAMETRIC MODEL FOR A SINGLE SAMPLE FROM A HOMOGENEOUS POPULATION

3.1 Introduction

Under a univariate model, a distribution is fitted to the lifetimes without using any covariates. The model must describe the basic underlying distribution of lifetimes.

Let $T$ be a non-negative continuous random variable representing lifetime from a homogeneous population. $Y = \ln(T)$ is used to represent the log-lifetime.

The standard way of fitting parametric models to an observed set of survival data is to use the method of maximum likelihood (refer to [5, page 319-322]).

A new method of fitting parametric models to an observed set of survival data will be introduced in this chapter and is called maximum likelihood estimation subject to constraints.
3.2 Standard Method of Maximum Likelihood Estimation

3.2.1 Introduction

In the univariate case, a log-linear model (a linear model in log-lifetime) could be fitted to a survival data set. This model is of the form

\[ Y = \ln T = \mu + \sigma W \]

where \( W \) is the error distribution, \( \mu \) is the location parameter and \( \sigma \) is the scale parameter.

The standard way of fitting such a model to an observed set of survival data is to use the method of maximum likelihood.

3.2.2 Likelihood function for the linear model in log-time

The likelihood function for this linear model in log-time may be derived as follows.

Consider the \( n \) pairs \((y_i, \delta_i)\) \( i = 1, 2, ..., n \) in the data set with \( y_i = \ln(t_i) \).

The basic form of the likelihood function for random right-censored continuous data is, from Equation 2.6.6, equal to

\[
L(\mu, \sigma) = \prod_{i=1}^{n} \left[ f_Y(y_i) \right]^{\delta_i} \cdot \left[ S_Y(y_i) \right]^{1-\delta_i} = \prod_{i=1}^{n} \left[ f_W \left( \frac{y_i - \mu}{\sigma} \right) \cdot \frac{1}{\sigma} \right]^{\delta_i} \cdot \left[ S_W \left( \frac{y_i - \mu}{\sigma} \right) \right]^{1-\delta_i} \quad (3.2.1)
\]

The log-likelihood function for random right-censored continuous data is then

\[
\ln L(\mu, \sigma) = \sum \delta_i \cdot \ln \left[ f_W \left( \frac{y_i - \mu}{\sigma} \right) \cdot \frac{1}{\sigma} \right] + \sum (1 - \delta_i) \cdot \ln \left[ S_W \left( \frac{y_i - \mu}{\sigma} \right) \right] \quad (3.2.2)
\]

with

the first sum over observed lifetimes (uncensored observations)
the second sum over right-censored observations.

The basic form of the likelihood function for interval-censored data follows from Equation 2.6.9 as

\[
L(\mu, \sigma) = \prod_{i=1}^{n} \left[ f_Y(y_i) \right]^{\delta_i} \cdot \left[ S_Y(y_i) \right]^{1-\delta_i} \cdot \left[ 1 - S_Y(y_i) \right]^{\delta_i} \cdot \left[ S_Y(b_i) - S_Y(y_i) \right]^{1-\delta_i}
\]
\[
= \prod_{i=1}^{n} \left[ f_W \left( \frac{y_i - \mu}{\sigma} \right) \cdot \frac{1}{\sigma} \right]^{\delta_i} \cdot \left[ S_W \left( \frac{y_i - \mu}{\sigma} \right) \right]^{1-\delta_i} \cdot \\
\left[ 1 - S_W \left( \frac{y_i - \mu}{\sigma} \right) \right]^{\delta_i} \cdot \left[ S_W \left( \frac{b_i - \mu}{\sigma} \right) - S_W \left( \frac{y_i - \mu}{\sigma} \right) \right]^{1-\delta_i}
\]

with \( b_i \) the lower end of a censoring interval.

The log-likelihood function for interval-censored data is

\[
\ln L(\mu, \sigma) = \sum \delta_i \cdot \ln \left[ f_W \left( \frac{y_i - \mu}{\sigma} \right) \cdot \frac{1}{\sigma} \right] + \sum (1 - \delta_i) \cdot \ln \left[ S_W \left( \frac{y_i - \mu}{\sigma} \right) \right] + \\
\sum (\delta_i) \cdot \ln \left[ 1 - S_W \left( \frac{y_i - \mu}{\sigma} \right) \right] + \sum (1 - \delta_i) \cdot \ln \left[ S_W \left( \frac{b_i - \mu}{\sigma} \right) - S_W \left( \frac{y_i - \mu}{\sigma} \right) \right]
\]

with

the first sum over observed lifetimes (uncensored observations)
the second sum over right-censored observations
the third sum over left-censored observations
the fourth sum over interval-censored observations.

### 3.2.3 Maximum likelihood estimators of the log-linear parameters

[5] shows how maximum likelihood estimators of the log-linear parameters \( \mu \) and \( \sigma \) associated with

- the extreme value distribution, the error distribution for the Weibull model
- the logistic distribution, the error distribution for the log-logistic model
- the normal distribution, the error distribution for the lognormal model

can be found numerically by the Newton-Raphson procedure (refer to [21]). When the iterative procedure has converged, the variance-covariance matrix of the log-linear parameter estimates can be approximated by the inverse of the information matrix, evaluated at the parameter estimates. The square roots of the diagonal elements of this matrix are then the standard errors of the estimated values of the log-linear parameters.

[4] shows how the LIFEREG procedure of the SAS statistical package computes these maximum likelihood estimators of the log-linear parameters \( \mu \) and \( \sigma \) and explains how the SAS
output must be interpreted. SAS allows for right-, left- and interval-censored data. The SAS programs appear in Appendix A. The variance-covariance matrix of the log-linear parameters \( \mu \) and \( \sigma \), obtained from the observed information matrix, are also available in the SAS package.

The invariance property of the maximum likelihood estimator provides that the maximum likelihood estimators of \( \lambda \) and \( \alpha \) at the Weibull and log-logistic are then given by

\[
\hat{\lambda} = \exp\left(\frac{-\hat{\mu}}{\hat{\sigma}}\right) \quad \text{and} \quad \hat{\alpha} = \frac{1}{\hat{\sigma}} \tag{3.2.5}
\]

An application of this standard technique to a reallife insurance company data set is done in chapter 5.

Applying the method of statistical differentials, also called delta method ([13, page 69-72]), leads to formulae for the standard errors of the estimates and the covariance between the two estimates.

\[
\begin{align*}
\text{var}(\hat{\lambda}) &= \exp\left(\frac{-2\hat{\mu}}{\hat{\sigma}}\right) \cdot \left[\frac{\text{var}(\hat{\mu})}{\hat{\sigma}^2} + \hat{\mu}^2 \frac{\text{var}(\hat{\sigma})}{\hat{\sigma}^4} - 2\hat{\mu} \frac{\text{cov}(\hat{\mu}, \hat{\sigma})}{\hat{\sigma}^3}\right] \tag{3.2.6} \\
\text{var}(\hat{\alpha}) &= \frac{\text{var}(\hat{\sigma})}{\hat{\sigma}^4} \tag{3.2.7} \\
\text{cov}(\hat{\lambda}, \hat{\alpha}) &= \exp\left(\frac{-\hat{\mu}}{\hat{\sigma}}\right) \cdot \left[\frac{\text{cov}(\hat{\mu}, \hat{\sigma})}{\hat{\sigma}^3} - \hat{\mu} \frac{\text{var}(\hat{\sigma})}{\hat{\sigma}^4}\right] \tag{3.2.8}
\end{align*}
\]

Once maximum likelihood estimates of the parameters \( \mu \) and \( \sigma \), or equivalently, \( \lambda \) and \( \alpha \) are computed, estimates of the survivor function and the hazard function are available for the distribution of \( T \) (or \( Y = \ln(T) \)), that is the Weibull (or extreme value), log-logistic (or logistic) and lognormal (or normal).

### 3.3 MLE subject to Constraints - A Fixed Censoring Time

#### 3.3.1 Introduction

Proposition 1, which is proved in [11], provides a method of finding the ML estimate for the mean vector of the exponential family, subject to certain constraints on the mean vector. From the estimate of the mean vector the estimates of the parameters in the model are computed.

Models can be easily formulated in terms of the implied constraints, which may be linear or non-linear in \( \mu \).
Proposition 1

Consider a random vector $y$, with probability function belonging to the exponential family. Let $g(\mu)$ be a continuous vector valued function of $\mu$, for which the first order partial derivatives exist. Let $G_\mu = \frac{\partial g(\mu)}{\partial \mu}$ be the derivative of $g(\mu)$ with respect to $\mu$ and $G_y = \frac{\partial g(\mu)}{\partial \mu} \bigg|_{\mu = y}$. The ML estimate of $\mu$ subject to the constraints $g(\mu) = 0$, is given by

$$\hat{\mu}_c = y - (G_\mu V_\mu)' (G_y V_\mu G'_\mu)^* g(y) + o(||y - \mu||)$$

(3.3.1)

This result implies that the MLE of $\mu$ must be obtained iteratively.

The variance-covariance matrix $V$ could be known, or it could be some function of $\mu$, say $V_\mu$. The iterative use of the estimation procedure thus depends on the form of $G_\mu$ and $V_\mu$.

The matrix $G_y V_\mu G'_\mu$ in Equation 3.3.1 should be non-singular, and therefore the inverse, denoted by $*$, is any generalized inverse (refer to [31, page 123]).

An expression for the asymptotic variance-covariance matrix of the estimator $\hat{\mu}_c$ is given in Proposition 2.

Proposition 2

The asymptotic variance-covariance matrix of $\hat{\mu}_c$ is given by

$$\text{cov}(\hat{\mu}_c) = V_\mu - (G_\mu V_\mu)' (G_y V_\mu G'_\mu)^* G_\mu V_\mu$$

(3.3.2)

In [10] these propositions are applied to provide a method for fitting certain continuous probability distributions to an observed frequency distribution. The method requires that some function of the cumulative distribution function must be written as a linear model. The estimation algorithm described in [11] is applied to find the maximum likelihood estimates of the parameters in this linear model. From these estimates, the estimates of the parameters of the distribution can be found. This fitting method will be described in the notation of the survival analysis problem under consideration, regarding the lapses of policies.

3.3.2 Notation for a fixed censoring time

Consider the simple experimental design, as described in [38], where all policies enter at the same time with $C$ the pre-assigned fixed censoring time. Instead of observing $X_1, X_2, ..., X_n$ only $T_1, T_2, ..., T_n$ are observed where

$$T_j = \begin{cases} 
X_j & \text{if } X_j \leq C \\
C & \text{if } X_j > C.
\end{cases}$$
The survival data, based on a sample of size $n$, can then be represented by pairs of random variables $(T_j, \delta_j)$ where $T_1, T_2, ..., T_n$ are independent identically distributed random variables, each with distribution function $F$ and density function $f$. $\delta_j$ is the survival status of the $j^{th}$ policy and indicates whether the lifetime for the $j^{th}$ policy corresponds to a lapse ($\delta_j = 1$) or is censored ($\delta_j = 0$).

A frequency distribution is formed when the observed values of the random variables $T_1, T_2, ..., T_n$ are grouped into $k$ adjacent, non-overlapping fixed lifetime intervals $[x_{j-1}; x_j)$ for $j = 1, 2, ..., k$ with $x_0 = 0$, $x_{k-1} = C$ and $x_k = \infty$, as shown in Table 3.1.

**Table 3.1: Relative frequency distribution of survival data - fixed censoring time**

</tr>
</tbody>
</table>

In Table 3.1, the last interval in the second column is an open interval containing all the censored lifetimes. The $x_j’s$, $j = 1, 2, ..., k - 1$ represent the upper class boundaries and $f_j$ denotes the observed frequency for the $j^{th}$ lifetime interval with $n$ the total number of observations $j = 1, 2, ..., k$.

Define

$$x = (x_1, x_2, ..., x_{k-1})'$$ as the $(k - 1) \times 1$ vector of upper class boundaries,

$$f = (f_1, f_2, ..., f_k)'$$ as the $k \times 1$ frequency vector and

$$p = \frac{f}{n}$$ as the $k \times 1$ relative frequency vector.

$f$ is a discrete random vector with a multinomial($n, \pi$) distribution, where $\pi = (\pi_1, \pi_2, ..., \pi_k)'$ and $\pi_i$ is the probability that an observed lifetime falls in the $i^{th}$ lifetime interval.

The relative frequency vector $p$ is an observed probability vector from a multinomial population with $np = f$ being multinomial($n, \pi$) distributed.

$$E(p) = \pi \quad \quad (3.3.3)$$
\[ \text{Cov}(p) = V = \frac{1}{n} \{ \text{diag}(\pi) - \pi \pi' \} \]  

(3.3.4)

Note that \( p \) is the MLE of \( \pi \) in the case of no constraints.

The MLE of \( \pi \) should be determined in terms of constraints imposed by the survival distribution to be fitted.

Note that \( f \) is a discrete random vector with a multinomial \((n, \pi)\) distribution and that the multinomial distribution is a member of the exponential family. Therefore Equation 3.3.1 of Proposition 1 in [11] can be reformulated in terms of the survival analysis problem under consideration.

The MLE of \( \pi \) subject to the constraints \( g(\pi) = 0 \) is

\[ \hat{\pi}_c = p - (G_\pi V_\pi)' (G_p V_\pi G_\pi')^* g(p) \]  

(3.3.5)

with

\[ G_\pi = \frac{\partial g(\pi)}{\partial \pi} \quad \text{and} \quad G_p = \frac{\partial g(\pi)}{\partial \pi} \bigg|_{\pi = p} \]  

(3.3.6)

This result implies that the MLE of \( \pi \) must be obtained iteratively by means of double iterations. The variance-covariance matrix \( V_\pi \) to be used is the estimated variance-covariance matrix of the multinomial distribution as stated in Equation 3.3.4.

A double iteration takes place over \( p \) and \( \pi \). For every value of \( \pi \) the iteration is performed over \( p \) to obtain a new estimate for \( \pi \).

The observed relative frequency vector \( p = p_0 \) is used as an initial estimate for \( \pi \) and \( p \).

In the first iteration over \( p \), the \( p \) in Equation 3.3.5 is replaced by this initial estimate, while the \( V_\pi \) in Equation 3.3.5 is estimated by \( \hat{V}_{p_0} = \frac{1}{n} \{ \text{diag}(p_0) - p_0 p_0' \} \) and the \( G_\pi \) in Equation 3.3.5 is replaced by \( G_{p_0} = \frac{\partial g(\pi)}{\partial \pi} \bigg|_{\pi = p_0} \). This results in a new estimate for \( \pi \).

In the second iteration over \( p \), only \( p \) in Equation 3.3.5 is replaced to obtain the second estimate for \( \pi \), while \( V_\pi \) and \( G_\pi \) are kept constant at \( \hat{V}_{p_0} \) and \( G_{p_0} \), since iteration at this stage is over \( p \). This is repeated until convergence is attained over \( p \). The final estimate for \( \pi \) at convergence during this first stage of iteration over \( p \) then becomes the second estimate for \( \pi \) in \( G_\pi \) and \( V_\pi \). Once again iteration takes place over \( p \), again starting with the observed relative frequency vector \( p = p_0 \) as estimate for \( \pi \) and keeping \( V_\pi \) and \( G_\pi \) constant at the estimated value at convergence. Iteration over \( p \) gives the third estimate for \( \pi \) in \( G_\pi \) and \( V_\pi \) and once again iteration takes place over \( p \), again starting with the initial \( p_0 \) vector as estimator for \( \pi \) and keeping \( V_\pi \) and \( G_\pi \) constant at the new estimated value at convergence. This procedure continues and convergence will be attained when the
final estimate for $\pi$ in the iteration over $p$ corresponds with the final estimate of $\pi$ in the iteration over $\pi$. This value then will be the MLE for $\pi_c$.

Define $\pi_s$ as the cumulative sum vector of the $\pi_j$'s. Hence

$$\pi_s = S \times \pi = \begin{pmatrix} \pi_1 \\ \pi_1 + \pi_2 \\ \vdots \\ \pi_1 + \pi_2 + \cdots + \pi_{k-1} \end{pmatrix}$$

where $S$ is a $(k-1) \times k$ matrix of the form

$$S = \begin{pmatrix} 1 & 0 & 0 & \cdots & 0 & 0 \\ 1 & 1 & 0 & \cdots & 0 & 0 \\ 1 & 1 & 1 & \cdots & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 1 & 1 & 1 & \cdots & 1 & 0 \end{pmatrix}$$

and

$$\pi = \begin{pmatrix} \pi_1 \\ \pi_2 \\ \vdots \\ \pi_k \end{pmatrix}$$

Let

$$x = \begin{pmatrix} x_1 \\ x_2 \\ \vdots \\ x_{k-1} \end{pmatrix}$$

then the cumulative distribution function

$$F(x) = S \times \pi = \pi_s$$  \hspace{1cm} (3.3.7)

It follows that

$$x = F^{-1}(\pi_s)$$  \hspace{1cm} (3.3.8)

specifies the constraints on the elements of $\pi_s$ and hence on $\pi$.

By using Equation 3.3.2 of Proposition 2, the asymptotic variance-covariance matrix of $\pi_c$ is

$$\text{cov}(\pi_c) = V - (G_{\pi} V)'(G_{\pi} V G'_{\pi})^{-1} G_{\pi} V$$  \hspace{1cm} (3.3.9)

Next it will be shown how the estimation procedure may be utilized to fit continuous survival distributions, such as the Weibull, log-logistic and lognormal to grouped survival data. For the Weibull and log-logistic survival distributions some function of the survival function $S(x) = 1 - F(x) = 1 - \pi_s$ may be written in terms of a linear model, from which the parameters of the survival distribution may be estimated. For the lognormal survival
distribution some function of the cumulative distribution function of the standard normal distribution may be expressed in terms of a **linear model**, from which the parameters of the lognormal distribution may be estimated.

The procedure to find the ML estimates of these three survival distributions can be easily implemented using a matrix algebra package, for example the SAS/IML procedure of the SAS System.

### 3.3.3 Fitting of a Weibull distribution to grouped survival data

From Equation 2.4.8 follows that

\[
\ln (-\ln S(t)) = \ln \lambda + \alpha \ln t
\]  

(3.3.10)

where \( t \) denotes the **continuous** survival time.

In the current notation for **grouped survival data** in terms of the vector of upper class boundaries, Equation 3.3.10 becomes

\[
\ln (-\ln S(x)) = \ln \lambda \cdot 1 - \alpha \cdot \ln x
\]  

(3.3.11)

or from \( S(x) = 1 - F(x) \)

\[
\ln \{-\ln(1 - F(x))\} = \ln \lambda \cdot 1 + \alpha \cdot \ln x
\]  

(3.3.12)

or from Equation 3.3.7

\[
\ln \{-\ln(1 - \pi_S)\} = \ln \lambda \cdot 1 + \alpha \cdot \ln x
\]  

(3.3.13)

\[
= \ln \lambda \cdot \begin{pmatrix} 1 \\ 1 \\ \vdots \\ 1 \end{pmatrix} + \alpha \cdot \begin{pmatrix} \ln x_1 \\ \ln x_2 \\ \vdots \\ \ln x_{k-1} \end{pmatrix}
\]

\[
= \begin{pmatrix} 1 & \ln x_1 \\ 1 & \ln x_2 \\ \vdots & \vdots \\ 1 & \ln x_{k-1} \end{pmatrix} \cdot \begin{pmatrix} \ln \lambda \\ \alpha \end{pmatrix}
\]

\[
\Rightarrow \ln \{-\ln(1 - \pi_S)\} = X_1 \cdot \begin{pmatrix} \ln \lambda \\ \alpha \end{pmatrix}
\]  

(3.3.14)
Equation 3.3.14 is a linear model in the parameters \( \ln \lambda \) and \( \alpha \). According to the general result for a linear model \( y = X\beta + \epsilon \) where \( E(y) = X\beta \) is equivalent to \( C \cdot E(y) = 0 \) with \( C = I - X(X'X)^{-1}X' \). Equation 3.3.14 is equivalent to

\[
\left( I - X_1(X_1'X_1)^{-1}X_1' \right) \cdot \ln \left( -\ln \left( 1 - \pi_S \right) \right) = 0 \\
\frac{C \cdot \ln \left( -\ln \left( 1 - \pi_S \right) \right)}{g(\pi)} = 0
\]

\( C \) is the projection matrix orthogonal to the columns of the design matrix \( X_1 \). Note that \( CX_1 = 0 \).

The function \( g(\pi) = 0 \) satisfies the conditions of Proposition 1 and the estimation algorithm in [11] can be used to estimate the parameters \( \lambda \) and \( \alpha \) of the Weibull distribution.

To summarize, the constraints imposed by the Weibull distribution are specified by

\[
g(\pi) = C \cdot \ln \left\{ -\ln \left( 1 - \pi_S \right) \right\} = C \cdot \ln \left\{ -\ln \left( 1 - S \cdot \pi \right) \right\} = 0 \quad (3.3.15)
\]

with

\[
C = I - X_1(X_1'X_1)^{-1}X_1' \quad \text{and} \quad X_1 = (1, \ln x) \quad . \quad (3.3.16)
\]

The derivative of \( g(\pi) \) with respect to \( \pi \) is given by

\[
G_\pi = \frac{\partial g(\pi)}{\partial \pi} \\
= C \cdot \left[ \text{diag} \left( \frac{1}{\ln(1 - S \cdot \pi)} \right) \right] \cdot \left[ \text{diag} \left( \frac{1}{(1 - S \cdot \pi)} \right) \right] \cdot (-S) \\
= -C \cdot \text{diag} \left( \frac{1}{\ln(1 - \pi_S)} \right) \cdot \text{diag} \left( \frac{1}{1 - \pi_S} \right) \cdot S \quad (3.3.17)
\]

\[
= -C \cdot D_1^{-1} \cdot D_2^{-1} \cdot S \quad (3.3.18)
\]

where \( D_1 \) and \( D_2 \) are diagonal matrices with the elements of \( \ln(1 - \pi_S) \) and \( (1 - \pi_s) \), respectively, on the main diagonal and

\[
S = \begin{pmatrix}
1 & 0 & 0 & \ldots & 0 & 0 \\
1 & 1 & 0 & \ldots & 0 & 0 \\
1 & 1 & 1 & \ldots & 0 & 0 \\
\vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\
1 & 1 & 1 & \ldots & 1 & 0
\end{pmatrix}
\]

From Equation 3.3.5 follows that the MLE of \( \pi \), the vector of probabilities, is

\[
\hat{\pi}_c = p - (G_\pi V)' (G_p V G_\pi' )^* \cdot C \cdot \ln \left\{ -\ln \left( 1 - S \cdot p \right) \right\} \quad (3.3.19)
\]
with \( p = \frac{f}{n} \) where \( f = (f_1, f_2, \ldots, f_k)' \) is the frequency vector being multinomial \((n, \pi)\) distributed.

The variance-covariance matrix \( V \) to be used is the estimated variance-covariance matrix of the multinomial distribution, which follows from Equation 3.3.4 as

\[
\hat{V} = \frac{1}{n} [\text{diag}(p) - pp']
\] (3.3.20)

Since Equation 3.3.19 is still a function of the unknown parameter \( \pi \), the double iterative procedure in [11] must be implemented. Once the iterative procedure in Equation 3.3.19 has converged, the estimated parameters of the Weibull distribution can be solved from

\[
\begin{pmatrix}
\ln \hat{\lambda} \\
\hat{\alpha}
\end{pmatrix} = (X_1'X_1)^{-1}X_1' \cdot \ln (\ln (1 - S \cdot \hat{\pi}_c)).
\] (3.3.21)

The estimated lambda parameter of the Weibull distribution then is

\[
\hat{\lambda} = \exp(\ln \hat{\lambda})
\]

and the estimated alpha parameter \( \hat{\alpha} \).

The SAS/IML program to fit a Weibull distribution to grouped survival data with a fixed censoring time appears in Appendix A.

3.3.4 Fitting of a log-logistic distribution to grouped survival data

From Equation 2.4.17 follows that

\[
\ln \left( \frac{1 - S(t)}{S(t)} \right) = \ln \lambda + \alpha \ln t
\] (3.3.22)

where \( t \) denotes the continuous survival time.

In the current notation for grouped survival data in terms of the vector of upper class boundaries, Equation 3.3.22 becomes

\[
\ln \left( \frac{1 - S(x)}{S(x)} \right) = \ln \left( \frac{F(x)}{1 - F(x)} \right) = \ln \left( \frac{\pi_S}{1 - \pi_S} \right) = \ln (\pi_S) - \ln (1 - \pi_S) = \ln \lambda \cdot 1 + \alpha \cdot \ln x
\] (3.3.23)
\[ \ln \lambda \cdot \begin{pmatrix} 1 \\ 1 \\ \ldots \\ 1 \end{pmatrix} + \alpha \cdot \begin{pmatrix} \ln x_1 \\ \ln x_2 \\ \ldots \\ \ln x_{k-1} \end{pmatrix} \]

\[ = \begin{pmatrix} 1 & \ln x_1 \\ 1 & \ln x_2 \\ \ldots & \ldots \\ 1 & \ln x_{k-1} \end{pmatrix} \cdot \begin{pmatrix} \ln \lambda \\ \alpha \end{pmatrix} \]

\[ = (1, \ln x) \cdot \begin{pmatrix} \ln \lambda \\ \alpha \end{pmatrix} \]

\[ \Rightarrow \ln \left( \frac{\pi_S}{1 - \pi_S} \right) = \ln(\pi_S) - \ln(1 - \pi_S) = X_1 \cdot \begin{pmatrix} \ln \lambda \\ \alpha \end{pmatrix} \quad (3.3.24) \]

Equation 3.3.24 is a **linear model** in the parameters \( \ln \lambda \) and \( \alpha \).

Similar to the case of the Weibull distribution, Equation 3.3.24 is equivalent to

\[ \left( I - X_1 (X_1' X_1)^{-1} X_1' \right) \cdot \ln \left( \frac{\pi_S}{1 - \pi_S} \right) = 0 \]

\[ C \cdot \ln \left( \frac{\pi_S}{1 - \pi_S} \right) = 0 \]

\[ g(\pi) = 0 \]

The function \( g(\pi) = 0 \) satisfies the conditions of Proposition 1 and the estimation algorithm can be used to estimate the parameters \( \lambda \) and \( \alpha \) of the log-logistic distribution.

To summarize, the constraints imposed by the log-logistic distribution are specified by

\[ g(\pi) = C \cdot \ln \left( \frac{\pi_S}{1 - \pi_S} \right) = C \cdot \ln \left( \frac{S \cdot \pi}{1 - S \cdot \pi} \right) = C \cdot \ln(S \cdot \pi) - \ln(1 - S \cdot \pi) = 0 \quad (3.3.25) \]

with

\[ C = I - X_1 (X_1' X_1)^{-1} X_1' \quad \text{and} \quad X_1 = (1, \ln x) \quad . \quad (3.3.26) \]

The derivative of \( g(\pi) \) with respect to \( \pi \) is given by

\[ G_\pi = \frac{\partial g(\pi)}{\partial \pi} \]

\[ = C \cdot \left[ \text{diag} \left( \frac{1}{S \cdot \pi} \right) \cdot S - \text{diag} \left( \frac{1}{1 - S \cdot \pi} \right) \cdot (-S) \right] \]
Parametric Model for a Single Sample from a Homogeneous Population

\[ C \cdot \left[ \text{diag} \left( \frac{1}{\pi_S} \right) + \text{diag} \left( \frac{1}{1 - \pi_S} \right) \right] \cdot S \]
\[ = C \cdot \left[ D_3^{-1} + D_2^{-1} \right] \cdot S \]

(3.3.27)

(3.3.28)

where \( D_3 \) and \( D_2 \) are diagonal matrices with the elements of \( \pi_S \) and \( 1 - \pi_S \), respectively, on the main diagonal and

\[
S = \begin{pmatrix}
1 & 0 & 0 & \ldots & 0 & 0 \\
1 & 1 & 0 & \ldots & 0 & 0 \\
1 & 1 & 1 & \ldots & 0 & 0 \\
\vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\
1 & 1 & 1 & \ldots & 1 & 0
\end{pmatrix}.
\]

The MLE of \( \pi \), the vector of probabilities, is in this case

\[
\hat{\pi}_c = p - (G_{pi}V)'(G_pVG_p')^{-1}C \cdot \ln \left\{ \frac{S \cdot p}{1 - S \cdot p} \right\}
\]

(3.3.29)

with \( p = \frac{f}{n} \) where \( f = (f_1, f_2, \ldots, f_k)' \) is the frequency vector being multinomial(\( n, \pi \)) distributed. The variance-covariance matrix \( V \) to be used is again the estimated variance-covariance matrix of the multinomial distribution, namely

\[
\hat{V} = \frac{1}{n} \left[ \text{diag}(p) - pp' \right]
\]

(3.3.30)

Since Equation 3.3.29 is still a function of the unknown parameter \( \pi \), the double iterative procedure must be implemented. Once the iterative procedure in Equation 3.3.29 has converged, the estimated parameters of the log-logistic distribution can be solved from

\[
\begin{pmatrix}
\ln \lambda \\
\hat{\alpha}
\end{pmatrix} = (X_1'X_1)^{-1}X_1' \cdot \ln \left\{ \frac{S \cdot \hat{\pi}_c}{1 - S \cdot \hat{\pi}_c} \right\}
\]

(3.3.31)

The estimated lambda parameter of the log-logistic distribution then is

\[
\hat{\lambda} = \exp(\ln \lambda)
\]

and the estimated alpha parameter \( \hat{\alpha} \).

The SAS/IML program to fit a log-logistic distribution to grouped survival data with a fixed censoring time appears in Appendix A.

### 3.3.5 Fitting of a lognormal distribution to grouped survival data

From Equation 2.5.10 follows that

\[
T \sim \text{lognormal}(\mu, \sigma^2) \iff \ln(T) \sim \text{normal}(\mu, \sigma^2).
\]

(3.3.32)
where \( T \) denotes the \textbf{continuous} survival time.

In the current notation for \textbf{grouped survival data} in terms of the vector of upper class boundaries, Equation 3.3.32 becomes

\[
x \sim \text{lognormal}(\mu, \sigma^2) \iff \ln x \sim \text{normal}(\mu, \sigma^2) \\
\iff \frac{\ln x - \mu \cdot 1}{\sigma} \sim \text{normal}(0, 1).
\]  (3.3.33)

From Equation 3.3.8 and Equation 3.3.33 follow that

\[
\frac{\ln x - \mu \cdot 1}{\sigma} = \Phi^{-1}(\pi_S)
\]

specifies the constraints on the elements of \( \pi_S = \pi \cdot S \) and hence on \( \pi \) where \( \Phi(\cdot) \) is the cumulative distribution function of the standard normal distribution.

\[
\Rightarrow \Phi^{-1}(\pi_S) = \frac{-\mu}{\sigma} \cdot 1 + \frac{1}{\sigma} \cdot \ln x
\]  (3.3.34)

\[
= \left(1, \ln x\right) \cdot \begin{pmatrix}
-\frac{\mu}{\sigma} \\
\frac{1}{\sigma}
\end{pmatrix}
\]

\[
\Rightarrow \Phi^{-1}(\pi_S) = X_1 \cdot \begin{pmatrix}
-\frac{\mu}{\sigma} \\
\frac{1}{\sigma}
\end{pmatrix}
\]  (3.3.35)

Equation 3.3.35 is a \textbf{linear model} in the parameters \( -\frac{\mu}{\sigma} \) and \( \frac{1}{\sigma} \).

Equation 3.3.35 is equivalent to

\[
(I - X_1 (X_1 'X_1)^{-1} X_1 ') \cdot \Phi^{-1}(\pi_S) = 0
\]

\[
C \cdot \Phi^{-1}(\pi_S) = 0
\]

\[
g(\pi) = 0
\]

The function \( g(\pi) = 0 \) satisfies the conditions of Proposition 1 and the estimation algorithm can be used to estimate the parameters \( \mu \) and \( \sigma^2 \) of the lognormal distribution.

To summarize, the constraints imposed by the lognormal distribution are specified by

\[
g(\pi) = C \cdot \Phi^{-1}(\pi_S) = C \cdot \Phi^{-1}(S \cdot \pi) = 0
\]  (3.3.36)
with
\[ C = I - X_1(X_1'X_1)^{-1}X_1' \text{ and } X_1 = (1, \ln x) . \] (3.3.37)

The derivative of \( g(\pi) \) with respect to \( \pi \) is
\[ G_\pi = \frac{\partial g(\pi)}{\partial \pi} = C \cdot \frac{\partial}{\partial \pi} \Phi^{-1}(S \cdot \pi) \cdot S \] (3.3.38)

In order to find \( \frac{\partial}{\partial \pi} \Phi^{-1}(S \cdot \pi) \) consider the scalar case. Let
\[ \pi_i = \Phi \left( \frac{\ln(x_i) - \mu}{\sigma} \right) = \Phi(z_i) . \]

Then \( \Phi^{-1}(\pi_i) = \frac{\ln(x_i) - \mu}{\sigma} = z_i \), so that
\[ \frac{\partial}{\partial \pi_i} \Phi^{-1}(\pi_i) = \frac{\partial z_i}{\partial \pi_i} = \frac{1}{\partial \pi_i / \partial z_i} = \frac{1}{\phi(z_i)} , \]
with \( \phi(\cdot) \) the probability density function of the standard normal distribution.

Applying this result to the vector of derivatives, Equation 3.3.38 becomes
\[ G_\pi = C \cdot \begin{bmatrix} \frac{1}{\phi \left( \frac{\ln x - \mu \cdot 1}{\sigma} \right)} \\ \text{diag} \left\{ \phi \left( \frac{\ln x - \mu \cdot 1}{\sigma} \right) \right\} \end{bmatrix} S . \] (3.3.39)

Since \( G_\pi \) depends on \( \mu \) and \( \sigma \) in the iterative procedure, these parameters will be estimated within the iterative stages and the final estimates will be obtained on convergence.

The SAS/IML program to fit a lognormal distribution to grouped survival data with a fixed censoring time appears in Appendix A.

### 3.3.6 A measure to compare the fit of survival distributions

A simple measure of discrepancy for comparing the fit of the survival distributions, is the statistic
\[ D_{X^2} = \frac{\chi^2_W}{n} \] (3.3.40)
where \( \chi^2_W \) is the Wald goodness of fit statistic (refer to [1]).

The Wald statistic in the survival analysis context is defined as
\[ \chi^2_W = g(p)' \cdot (G_p V G_p')^* \cdot g(p) . \]
with $V = \frac{1}{n} [\text{diag}(p) - pp']$ the estimated variance-covariance matrix of the multinomial distribution.

When fitting a Weibull distribution

$$g(p) = C \ln \left\{ -\ln (1 - S \cdot p) \right\}$$

and

$$G_p = -C \cdot \text{diag} \left( \frac{1}{\ln (1 - S \cdot p)} \right) \cdot \text{diag} \left( \frac{1}{1 - S \cdot p} \right) \cdot S.$$ 

When fitting a log-logistic distribution

$$g(p) = C \cdot \left[ \ln (S \cdot p) - \ln (1 - S \cdot p) \right]$$

and

$$G_p = C \cdot \left[ \text{diag} \left( \frac{1}{S \cdot p} \right) + \text{diag} \left( \frac{1}{1 - S \cdot p} \right) \right] \cdot S.$$ 

When fitting a lognormal distribution

$$g(p) = C \Phi^{-1}(S \cdot \pi)$$

and

$$G_p = C \cdot \left[ \frac{1}{\text{diag} \left( \frac{\ln x - \mu_p \cdot 1}{\sigma_p} \right) \cdot S} \right]$$

with $\mu_p$ and $\sigma_p$ the estimated values of $\mu$ and $\sigma$ at the first iteration.

The number of degrees of freedom equals the number of independent constraints imposed by the model. In general, a value of $D_{\chi^2}$ less than 0.05 may be regarded as a good fit.

The Pearson's $\chi^2$ statistic and the maximum likelihood $\chi^2$ statistic (refer to [38, page 16-18] are asymptotically equivalent to the Wald statistic.

The calculation of the Wald statistic and the associated discrepancy is shown in the SAS/IML programs in Appendix A.
3.4 MLE subject to Constraints - Staggered Entry

3.4.1 Introduction

Consider the following experimental design as illustrated in Figure 3.1. Policies enter the study at different times (staggered entry). The event to be occurred is a lapse. The lifetime of a policy is measured from inception date up to the lapsing date. If the lapsing date is prior to a fixed termination date (cutoff date) of the study, determined in advance, then the lifetime is observed (an uncensored observation). If a policy is still in force (alive) when the termination point is reached, the lifetime of this policy is right-censored. Random entries to the study are assumed. This type of censoring is known as random right-censoring. The censoring is noninformative in that the lapse and censoring times are independent.

3.4.2 Notation for staggered entry

$C_j$ is the potential censoring time for the $j^{th}$ policy, associated with lifetime $X_j$. $C_1, C_2, ..., C_n$ are independent identically distributed random variables, each with distribution function $G$ and density function $g$. A further assumption that $X_i$ and $C_i$ are independent is made.

The survival data, based on a sample of size $n$, can then be represented by pairs $(T_1, \delta_1), (T_2, \delta_2), ..., (T_n, \delta_n)$ where

$$T_j = \min(X_j, C_j) \text{ for the } j^{th} \text{ policy}$$

$$\delta_j = \begin{cases} 
1 & \text{if } X_j \leq C_j, \text{ that is, } X_j \text{ is not censored} \\
0 & \text{if } X_j > C_j, \text{ that is, } X_j \text{ is censored}
\end{cases}$$

$T_1, T_2, ..., T_n$ are independent identically distributed random variables with distribution function $F$ if $T_j = X_j$ and distribution function $G$ if $T_j = C_j$. 
Figure 3.1: Experimental design for staggered entry of policies
To set notation for the staggered entry case, assume for illustration purposes four different entry times for the policies. The lifetimes of the $n_1$ policies that enter the study at the first entry time (called the first sample of size $n_1$) can be grouped into $k$ adjacent, non-overlapping fixed intervals

$$I_j = [x_{j-1}; x_j) \quad j = 1, 2, ..., k$$

with $x_0 = 0$ and $x_k = \infty$. The last interval is an open interval containing all the censored lifetimes of the first sample.

The lifetimes of the $n_2$ policies that enter the study at the second entry time (called the second sample of size $n_2$) can be grouped into $(k - 1)$ adjacent, non-overlapping fixed intervals

$$I_j = [x_{j-1}; x_j) \quad j = 1, 2, ..., k - 1$$

with $x_0 = 0$ and $x_{k-1} = \infty$. The last interval is an open interval containing all the censored lifetimes of the second sample.

The lifetimes of the $n_3$ policies that enter the study at the third entry time (called the third sample of size $n_3$) can be grouped into $(k - 2)$ adjacent, non-overlapping fixed intervals

$$I_j = [x_{j-1}; x_j) \quad j = 1, 2, ..., k - 2$$

with $x_0 = 0$ and $x_{k-2} = \infty$. The last interval is an open interval containing all the censored lifetimes of the third sample.

The lifetimes of the $n_4$ policies that enter the study at the last entry time (called the fourth sample of size $n_4$) can be grouped into $(k - 3)$ adjacent, non-overlapping fixed intervals

$$I_j = [x_{j-1}; x_j) \quad j = 1, 2, ..., k - 3$$

with $x_0 = 0$ and $x_{k-3} = \infty$. The last interval is an open interval containing all the censored lifetimes of the fourth sample.

Four frequency distributions are formed when the observed and censored lifetimes of all the policies are grouped into the different lifetime intervals. The total number of observations in the data set is $n = n_1 + n_2 + n_3 + n_4$.

The four vectors of upper class boundaries are defined as follows:

- $x_1 = (x_1, x_2, ..., x_{k-1})'$ is a $(k - 1) \times 1$ vector (sample 1)
- $x_2 = (x_1, x_2, ..., x_{k-2})'$ is a $(k - 2) \times 1$ vector (sample 2)
- $x_3 = (x_1, x_2, ..., x_{k-3})'$ is a $(k - 3) \times 1$ vector (sample 3)
- $x_4 = (x_1, x_2, ..., x_{k-4})'$ is a $(k - 4) \times 1$ vector (sample 4)
The four relative frequency vectors are observed probability vectors from four independent multinomial populations. Let \( p_1, p_2, p_3 \) and \( p_4 \) be the four relative frequency vectors.

\[
\begin{align*}
p_1 &= (p_{1,1}, p_{1,2}, p_{1,3}, \ldots, p_{1,k})' \\
p_2 &= (p_{2,1}, p_{2,2}, p_{2,3}, \ldots, p_{2,k-1})' \\
p_3 &= (p_{3,1}, p_{3,2}, p_{3,3}, \ldots, p_{3,k-2})' \\
p_4 &= (p_{4,1}, p_{4,2}, p_{4,3}, \ldots, p_{4,k-3})'
\end{align*}
\]

is an observed probability vector (sample 1)

is an observed probability vector (sample 2)

is an observed probability vector (sample 3)

is an observed probability vector (sample 4)

Each sample is from a multinomial population \( i = 1, 2, 3, 4 \) with

\[
E(p_i) = \pi_i \\
Cov(p_i) = V_i = \frac{1}{n_i} \left[ \text{diag}(\pi_i) - \frac{1}{n_i} \pi_i \pi_i' \right]
\]

where \( \pi_1 = (\pi_{1,1}, \pi_{1,2}, \pi_{1,3}, \ldots, \pi_{1,k})' \) is a \( k \times 1 \) probability vector

\( \pi_2 = (\pi_{2,1}, \pi_{2,2}, \pi_{2,3}, \ldots, \pi_{2,k-1})' \) is a \((k-1)\times1\) probability vector

\( \pi_3 = (\pi_{3,1}, \pi_{3,2}, \pi_{3,3}, \ldots, \pi_{3,k-2})' \) is a \((k-2)\times1\) probability vector

\( \pi_4 = (\pi_{4,1}, \pi_{4,2}, \pi_{4,3}, \ldots, \pi_{4,k-3})' \) is a \((k-3)\times1\) probability vector

\( \pi_{i,j} \) is the probability that an observation from sample \( i \) will fall in the \( j^{th} \) interval, that is the interval probability of the \( j^{th} \) interval from sample \( i \) \( i = 1, 2, 3, 4 \) \( j = 1, 2, \ldots, k \).

\[ \Rightarrow \quad p_1, p_2, p_3 \text{ and } p_4 \text{ are four observed probability vectors corresponding to} \]

\[ n_ip_i \text{ being multinomial}(n_i; \pi_i) \]

with \( n_i \) the number of observations in the \( i^{th} \) sample \( i = 1, 2, 3, 4 \).

Table 3.2 gives the relative frequency distributions of the four samples.

The vectors \( x_i \quad i = 1, 2, 3, 4 \) of upper class boundaries for the \( i^{th} \) sample (entry group) are

\[
\begin{align*}
x_1 &= \begin{pmatrix} x_1 \\ x_2 \\ \vdots \\ x_{k-1} \end{pmatrix} \\
x_2 &= \begin{pmatrix} x_1 \\ x_2 \\ \vdots \\ x_{k-2} \end{pmatrix} \\
x_3 &= \begin{pmatrix} x_1 \\ x_2 \\ \vdots \\ x_{k-3} \end{pmatrix} \quad \text{and} \\
x_4 &= \begin{pmatrix} x_1 \\ x_2 \\ \vdots \\ x_{k-4} \end{pmatrix}
\end{align*}
\]
Define the combined vector of relative frequencies (combined observed probability vector) as $p' = (p'_1, p'_2, p'_3, p'_4)$ and the combined probability vector as $\pi' = (\pi'_1, \pi'_2, \pi'_3, \pi'_4)$.

Note that $p$ is the MLE of $\pi$ in the case of no constraints. $\pi$ is to be estimated under certain constraints.

The MLE of $\pi$ should be determined in terms of

- constraints imposed by the experimental design
- constraints imposed by the survival distribution to be fitted
Table 3.2: Relative frequency distributions of survival data - staggered entry

3.4.3 Definition of Constraints

**Constraints imposed by the survival distribution to be fitted**

**Constraints imposed by the Weibull distribution**

A Weibull distribution with parameters \( \lambda \) and \( \alpha \) subject to the constraints \( \pi_S \) can be written from Equation 3.3 .13 as

\[
\ln(-\ln(1 - \pi_S)) = \ln \lambda \cdot 1 + \alpha \cdot \ln x
\]

**Constraints imposed by the log-logistic distribution**

A log-logistic distribution with parameters \( \lambda \) and \( \alpha \) subject to the constraints \( \pi_S \) can be written from Equation 3.3 .23 as

\[
\ln(\pi_S) - \ln(1 - \pi_S) = \ln \lambda \cdot 1 + \alpha \cdot \ln x
\]

**Constraints imposed by the lognormal distribution**

A lognormal distribution with parameters \( \mu \) and \( \sigma^2 \) subject to the constraints \( \pi_S \) can be written from Equation 3.3 .34 as

\[
\Phi^{-1}(\pi_S) = -\frac{\mu}{\sigma} \cdot 1 + \frac{1}{\sigma} \cdot \ln x
\]
Constraints imposed by the experimental design

Consider Figure 3.2, illustrating the constraints imposed by the experimental design.

- \( \pi_{1,j} = \pi_{2,j} = \pi_{3,j} = \pi_{4,j} \quad j = 1, 2, ..., k - 4 \)

- \( \pi_{1,k} + \pi_{1,k-1} + \pi_{1,k-2} + \pi_{1,k-3} = \pi_{2,k-1} + \pi_{2,k-2} + \pi_{2,k-3} = \pi_{3,k-2} + \pi_{3,k-3} = \pi_{4,k-3} \)

- \( \pi_{1,k-2} = \pi_{2,k-2} \)
- \( \pi_{1,k-3} = \pi_{2,k-3} \)

where \( \pi_{i,j} \) = probability of an observation from sample \( i \) will fall in the \( j^{th} \) interval
\( = \) interval probability of \( j^{th} \) interval from sample \( i \) \( i = 1, 2, 3, 4 \quad j = 1, 2, ..., k \)

These constraints can be written as

- \( 1 \cdot \pi_{1,j} - 1 \cdot \pi_{2,j} = 0 \)
- \( 1 \cdot \pi_{1,j} - 1 \cdot \pi_{3,j} = 0 \)
- \( 1 \cdot \pi_{1,j} - 1 \cdot \pi_{4,j} = 0 \quad j = 1, 2, ..., k - 4 \)

- \( 1 \cdot \pi_{1,k} + 1 \cdot \pi_{1,k-1} + 1 \cdot \pi_{1,k-2} + 1 \cdot \pi_{1,k-3} - 1 \cdot \pi_{2,k-1} - 1 \cdot \pi_{2,k-2} - 1 \cdot \pi_{2,k-3} = 0 \)
- \( 1 \cdot \pi_{1,k} + 1 \cdot \pi_{1,k-1} + 1 \cdot \pi_{1,k-2} + 1 \cdot \pi_{1,k-3} - 1 \cdot \pi_{3,k-2} - 1 \cdot \pi_{3,k-3} = 0 \)
- \( 1 \cdot \pi_{1,k} + 1 \cdot \pi_{1,k-1} + 1 \cdot \pi_{1,k-2} + 1 \cdot \pi_{1,k-3} - 1 \cdot \pi_{4,k-3} = 0 \)

- \( 1 \cdot \pi_{1,k-2} - 1 \cdot \pi_{2,k-2} = 0 \)
- \( 1 \cdot \pi_{1,k-3} - 1 \cdot \pi_{2,k-3} = 0 \)
Figure 3.2: Constraints imposed by the experimental design
These constraints in matrix form are $G \cdot \pi = 0$ with $\pi = (\pi_1, \pi_2, \pi_3, \pi_4)$ where

$\pi_1 = (\pi_{1,1}, \pi_{1,2}, \pi_{1,3}, ..., \pi_{1,k})'$ is a $k \times 1$ probability vector

$\pi_2 = (\pi_{2,1}, \pi_{2,2}, \pi_{2,3}, ..., \pi_{2,k-1})'$ is a $(k - 1) \times 1$ probability vector

$\pi_3 = (\pi_{3,1}, \pi_{3,2}, \pi_{3,3}, ..., \pi_{3,k-2})'$ is a $(k - 2) \times 1$ probability vector

$\pi_4 = (\pi_{4,1}, \pi_{4,2}, \pi_{4,3}, ..., \pi_{4,k-3})'$ is a $(k - 3) \times 1$ probability vector

and

$$G = \begin{pmatrix} I & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ I & 0 & 0 & 0 & 0 & 0 & I & 0 & 0 & 0 \\ I & 0 & 0 & 0 & 0 & 0 & 0 & I & 0 & 0 \\ 0' & 1 & 1 & 1 & 1 & 0' & -1 & -1 & 0' & 0 \\ 0' & 1 & 1 & 1 & 1 & 0' & 0 & 0 & 0' & -1 \\ 0' & 1 & 1 & 1 & 1 & 0' & 0 & 0 & 0' & -1 \\ 0' & 0 & 1 & 0 & 0 & 0' & 0 & -1 & 0 & 0 \\ 0' & 1 & 0 & 0 & 0 & 0' & -1 & 0 & 0 & 0' \end{pmatrix}.$$

3.4.4 Method of maximum likelihood estimation subject to constraints: staggered entry

The technique of maximum likelihood estimation subject to constraints is implemented in the following way:

1. One survival model is fitted under constraints imposed by the Weibull/log-logistic/lognormal distribution over the four entry groups.

2. Four survival models (Weibull/log-logistic/lognormal models), one for each entry time, are fitted under constraints imposed by the Weibull/log-logistic/lognormal distribution and under further constraints that

   - $\lambda_i$'s are equal and $\alpha_i$'s are equal when fitting a Weibull or log-logistic

   or

   - $\mu_i$'s are equal and $\sigma_i$'s are equal when fitting a lognormal

3. A joint histogram is fitted to the four histograms of the four relative frequency distributions under constraints imposed by the experimental design.
3.4.5 Fitting of one survival distribution to the four histograms

Fitting of one Weibull distribution to the four histograms

Recall that a Weibull distribution with parameters $\lambda$ and $\alpha$ under the constraints $\pi_S$ can be written as

$$\ln \{ -\ln(1 - \pi_S) \} = \ln \lambda \cdot 1 + \alpha \cdot \ln x$$ \hspace{1cm} (3.4.1)

or

$$\ln \{ -\ln(1 - \pi_S) \} = \ln \lambda \cdot \begin{pmatrix} 1 \\ 1 \\ 1 \\ 1 \end{pmatrix} + \alpha \cdot \begin{pmatrix} \ln x_1 \\ \ln x_2 \\ \ln x_3 \\ \ln x_4 \end{pmatrix}$$

$$= \begin{pmatrix} 1 \\ 1 \\ 1 \\ 1 \end{pmatrix} \begin{pmatrix} \ln x_1 \\ \ln x_2 \\ \ln x_3 \\ \ln x_4 \end{pmatrix} \cdot \begin{pmatrix} \ln \lambda \\ \alpha \end{pmatrix}$$

$$\Rightarrow \ln \{ -\ln(1 - \pi_S) \} = X_1 \cdot \begin{pmatrix} \ln \lambda \\ \alpha \end{pmatrix}$$ \hspace{1cm} (3.4.2)

where

$$x_1 = \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ \vdots \\ \vdots \\ \vdots \\ x_{k-1} \end{pmatrix} \hspace{1cm} x_2 = \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ \vdots \\ \vdots \\ \vdots \\ x_{k-2} \end{pmatrix} \hspace{1cm} x_3 = \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ \vdots \\ \vdots \\ \vdots \\ x_{k-3} \end{pmatrix} \hspace{1cm} x_4 = \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ \vdots \\ \vdots \\ \vdots \\ x_{k-4} \end{pmatrix}$$

Equation 3.4.2 is a linear model in the parameters $\ln \lambda$ and $\alpha$. This model is equivalent to

$$\left( I - X_1 (X_1'X_1)^{-1}X_1' \right) \cdot \ln \{ -\ln(1 - \pi_S) \} = 0$$

$$C \cdot \ln \{ -\ln(1 - \pi_S) \} = 0$$

$$g(\pi) = 0$$
$C$ is the projection matrix orthogonal to the columns of the design matrix $X_1$. Note that $CX_1 = 0$.

The function $g(\pi) = 0$ satisfies the conditions of Proposition 1 and the estimation algorithm can be used to estimate the $\lambda$ and $\alpha$ of the Weibull distribution.

To summarize, the constraints imposed by the Weibull distribution are specified by

$$g(\pi) = C \cdot \ln \{-\ln(1 - \pi S')\} = C \cdot \ln \{-\ln(1 - S \cdot \pi)\} = 0 \quad (3.4 .3)$$

with

$$C = I - X_1 (X_1' X_1)^{-1} X_1' . \quad (3.4 .4)$$

The derivative of $g(\pi)$ with respect to $\pi$ is

$$G_\pi = \frac{\partial g(\pi)}{\partial \pi} = -C \cdot \text{diag} \left( \frac{1}{\ln(1 - \pi S)} \right) \cdot \text{diag} \left( \frac{1}{1 - \pi S} \right) \cdot S \quad (3.4 .5)$$

$$= -C \cdot D_1^{-1} \cdot D_2^{-1} \cdot S \quad (3.4 .6)$$

where

$D_1$ and $D_2$ are diagonal matrices with the elements of $\ln(1 - \pi S)$ and $(1 - \pi S)$, respectively, on the main diagonal and $S$ is a block-diagonal matrix created from four matrices $S_1, S_2, S_3$ and $S_4$ associated with the four entry periods.

The estimated vector of probabilities is in this case

$$\hat{\pi}_c = p - (G_\pi V)' (G_p V G_\pi')^* \cdot C \cdot \ln \{-\ln(1 - S \cdot p)\} \quad (3.4 .7)$$

with $p' = (p_1', p_2', p_3', p_4')$ where $p_1 = (p_{1,1}, p_{1,2}, p_{1,3}, \ldots, p_{1,6})'$, $p_2 = (p_{2,1}, p_{2,2}, p_{2,3}, \ldots, p_{2,6})'$, $p_3 = (p_{3,1}, p_{3,2}, p_{3,3}, \ldots, p_{3,6})'$ and $p_4 = (p_{4,1}, p_{4,2}, p_{4,3}, \ldots, p_{4,6})'$ are four relative frequency vectors corresponding to $n_i p_i$ being multinomial($n_i; \pi_i$) $i = 1, 2, 3, 4$ distributed.

The variance-covariance matrix $V$ to be used is the estimated variance-covariance matrix of the multinomial distribution for each entry period.

$$\Rightarrow \hat{V} = \text{block}(\hat{V}_1, \hat{V}_2, \hat{V}_3, \hat{V}_4)$$

and

$$\hat{V}_i = \frac{1}{n_i} [\text{diag}(p_i) - p_i p_i'] \quad i = 1, 2, 3, 4$$
In the notation for staggered entry of policies, as described in Table 3.2 with four entry periods and k, the number of class intervals, for illustration purposes equal to seven,

\[ p_1 = (p_{1,1}, p_{1,2}, p_{1,3}, p_{1,4}, p_{1,5}, p_{1,6}, p_{1,7})' \] is a 7 \times 1 relative frequency vector
\[ p_2 = (p_{2,1}, p_{2,2}, p_{2,3}, p_{2,4}, p_{2,5}, p_{2,6})' \] is a 6 \times 1 relative frequency vector
\[ p_3 = (p_{3,1}, p_{3,2}, p_{3,3}, p_{3,4}, p_{3,5})' \] is a 5 \times 1 relative frequency vector
\[ p_4 = (p_{4,1}, p_{4,2}, p_{4,3}, p_{4,4})' \] is a 4 \times 1 relative frequency vector

\[ \pi_1 = (\pi_{1,1}, \pi_{1,2}, \pi_{1,3}, \pi_{1,4}, \pi_{1,5}, \pi_{1,6}, \pi_{1,7})' \] is a 7 \times 1 probability vector
\[ \pi_2 = (\pi_{2,1}, \pi_{2,2}, \pi_{2,3}, \pi_{2,4}, \pi_{2,5}, \pi_{2,6})' \] is a 6 \times 1 probability vector
\[ \pi_3 = (\pi_{3,1}, \pi_{3,2}, \pi_{3,3}, \pi_{3,4}, \pi_{3,5})' \] is a 5 \times 1 probability vector
\[ \pi_4 = (\pi_{4,1}, \pi_{4,2}, \pi_{4,3}, \pi_{4,4})' \] is a 4 \times 1 probability vector.

\( S \) is a 18 \times 22 block-diagonal matrix, that is

\[ S = \text{block}(S_1, S_2, S_3, S_4) \]

with

\[
S_1 = \begin{pmatrix}
1 & 0 & 0 & 0 & 0 & 0 & 0 \\
1 & 1 & 0 & 0 & 0 & 0 & 0 \\
1 & 1 & 1 & 0 & 0 & 0 & 0 \\
1 & 1 & 1 & 1 & 0 & 0 & 0 \\
1 & 1 & 1 & 1 & 1 & 0 & 0 \\
1 & 1 & 1 & 1 & 1 & 1 & 0
\end{pmatrix}
\]

\[
S_2 = \begin{pmatrix}
1 & 0 & 0 & 0 & 0 & 0 & 0 \\
1 & 1 & 0 & 0 & 0 & 0 & 0 \\
1 & 1 & 1 & 0 & 0 & 0 & 0 \\
1 & 1 & 1 & 1 & 0 & 0 & 0 \\
1 & 1 & 1 & 1 & 1 & 0 & 0
\end{pmatrix}
\]

\[
S_3 = \begin{pmatrix}
1 & 0 & 0 & 0 & 0 & 0 \\
1 & 1 & 0 & 0 & 0 & 0 \\
1 & 1 & 1 & 0 & 0 & 0 \\
1 & 1 & 1 & 1 & 0 & 0
\end{pmatrix}
\]

\[
S_4 = \begin{pmatrix}
1 & 0 & 0 & 0 \\
1 & 1 & 0 & 0 \\
1 & 1 & 1 & 0
\end{pmatrix}
\]
The matrix $S$ is given below.

$$
S = 
\begin{pmatrix}
1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
1 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
1 & 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 0
\end{pmatrix}.
$$

Note that $\hat{\mathbf{V}}_1$ is a 7 × 7, $\hat{\mathbf{V}}_2$ is a 6 × 6, $\hat{\mathbf{V}}_3$ is a 5 × 5 and $\hat{\mathbf{V}}_4$ is a 4 × 4 matrix so that $\hat{\mathbf{V}}$ is a 22 × 22 matrix.

Since Equation 3.4 .7 is still a function of the unknown parameter $\pi$, the double iterative procedure must be implemented. Once the iterative procedure in Equation 3.4 .7 has converged, the estimated parameters of the Weibull distribution can be solved from

$$
\begin{pmatrix}
\ln \lambda \\
\alpha
\end{pmatrix} = (X_1'X_1)^{-1}X_1'\ln \{-\ln(1 - \hat{\mathbf{S}} \cdot \hat{\pi}_c)\}.
$$

(3.4 .8)

The estimated lambda parameter of the Weibull distribution then is

$$
\hat{\lambda} = \exp(\ln \lambda)
$$

and the estimated alpha parameter $\hat{\alpha}$.

The SAS/IML program to fit a Weibull model to grouped survival data with staggered entry of policies appears in Appendix A.

**Fitting of one log-logistic distribution to the four histograms**

Recall that a log-logistic distribution with parameters $\lambda$ and $\alpha$ under the constraints $\pi_S$ can be written as

$$
\ln (\pi_S) - \ln (1 - \pi_S) = \ln \lambda \cdot 1 + \alpha \cdot \ln x
$$

(3.4 .9)
or

\[
\ln \left( \frac{\pi_S}{1 - \pi_S} \right) = \ln(\pi_S) - \ln(1 - \pi_S)
\]

\[
= \ln \lambda \cdot \begin{pmatrix} 1 \\ 1 \\ 1 \\ 1 \end{pmatrix} + \alpha \cdot \begin{pmatrix} \ln x_1 \\ \ln x_2 \\ \ln x_3 \\ \ln x_4 \end{pmatrix}
\]

\[
= \begin{pmatrix} 1 & \ln x_1 \\ 1 & \ln x_2 \\ 1 & \ln x_3 \\ 1 & \ln x_4 \end{pmatrix} \cdot \begin{pmatrix} \ln \lambda \\ \alpha \end{pmatrix}
\]

\[
\Rightarrow \ln \left( \frac{\pi_S}{1 - \pi_S} \right) = X_1 \cdot \begin{pmatrix} \ln \lambda \\ \alpha \end{pmatrix} \quad (3.4.10)
\]

where

\[
x_1 = \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ \vdots \\ \vdots \\ x_{k-1} \end{pmatrix}, \quad x_2 = \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ \vdots \\ \vdots \\ x_{k-2} \end{pmatrix}, \quad x_3 = \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ \vdots \\ \vdots \\ x_{k-3} \end{pmatrix}, \quad \text{and} \quad x_4 = \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ \vdots \\ x_{k-4} \end{pmatrix}
\]

Equation 3.4.10 is a **linear model** in the parameters \( \ln \lambda \) and \( \alpha \). This model is equivalent to

\[
(I - X_1(X_1'X_1)^{-1}X_1') \cdot \ln \left( \frac{\pi_S}{1 - \pi_S} \right) C \cdot \ln \left( \frac{\pi_S}{1 - \pi_S} \right) = 0
\]

\[
g(\pi) = 0
\]

\( C \) is the projection matrix orthogonal to the columns of the design matrix \( X_1 \). Note that \( CX_1 = 0 \).

The function \( g(\pi) = 0 \) satisfies the conditions of Proposition 1 and the estimation algorithm can be used to estimate the \( \lambda \)'s and \( \alpha \)'s of the log-logistic distribution.
To summarize, the constraints imposed by the log-logistic distribution are specified by

\[ g(\pi) = C \ln \left( \frac{\pi S}{1 - \pi S} \right) = C \ln \left[ \frac{S \cdot \pi}{1 - S \cdot \pi} \right] = C \left[ \ln(S \cdot \pi) - \ln(1 - S \cdot \pi) \right] = 0 \]  

(3.4 .11)

with

\[ C = I - X_1(X_1'X_1)^{-1}X_1' \]  

(3.4 .12)

The derivative of \( g(\pi) \) with respect to \( \pi \) is

\[ G_\pi = \frac{\partial g(\pi)}{\partial \pi} = C \left[ \text{diag} \left( \frac{1}{\pi S} \right) + \text{diag} \left( \frac{1}{1 - \pi S} \right) \right] \cdot S \]  

(3.4 .13)

\[ = C \cdot D_3^{-1} + D_2^{-1} \cdot S \]  

(3.4 .14)

where

\( D_3 \) and \( D_2 \) are diagonal matrices with the elements of \( \pi_S \) and \( 1 - \pi_S \), respectively, on the main diagonal. The matrix \( S \) is the same \( S \) matrix that was used when fitting a Weibull model.

The estimated vector of probabilities in this case is

\[ \hat{\pi}_c = p - (G_\pi V') (G_p V G'_\pi)^* \cdot C \ln \left( \frac{S \cdot p}{1 - S \cdot p} \right) \]  

(3.4 .15)

with \( p' = (p'_1, p'_2, p'_3, p'_4) \) where \( p_1 = (p_{1,1}, p_{1,2}, p_{1,3}, ..., p_{1,k})' \) \( p_2 = (p_{2,1}, p_{2,2}, p_{2,3}, ..., p_{2,k-1})' \) \( p_3 = (p_{3,1}, p_{3,2}, p_{3,3}, ..., p_{3,k-2})' \) and \( p_4 = (p_{4,1}, p_{4,2}, p_{4,3}, ..., p_{4,k-3})' \) are four relative frequency vectors corresponding to \( n_i p_i \) being multinomial\((n_i; \pi_i) \ i = 1, 2, 3, 4 \) distributed. The variance-covariance matrix \( V \) to be used is the estimated variance-covariance matrix of the multinomial distribution for each entry period.

Since Equation 3.4 .15 is still a function of the unknown parameter \( \pi \), the double iterative procedure must be implemented. Once the iterative procedure in Equation 3.4 .15 has converged, the estimated parameters of the log-logistic distribution can be solved from

\[ \left( \ln \hat{\lambda} \over \hat{\nu} \right) = (X_1'X_1)^{-1}X_1' \cdot \ln \left( \frac{S \cdot \hat{\pi}_c}{1 - S \cdot \hat{\pi}_c} \right) \]  

(3.4 .16)

The estimated lambda parameter of the log-logistic distribution then is

\[ \hat{\lambda} = \exp(\ln \hat{\lambda}) \]
and the estimated alpha parameter $\hat{\alpha}$.

The SAS/IML program to fit a log-logistic model to grouped survival data with staggered entry of policies appears in Appendix A.

**Fitting of one lognormal distribution to the four histograms**

Recall that a lognormal distribution with parameters $\mu$ and $\sigma^2$ under the constraints $\pi_s$ can be written as

$$
\Phi^{-1}(\pi_s) = -\frac{\mu}{\sigma} \cdot 1 + \frac{1}{\sigma} \cdot \ln x
$$

$$
= -\frac{\mu}{\sigma} \cdot \begin{pmatrix} 1 \\ 1 \\ 1 \\ 1 \end{pmatrix} + \frac{1}{\sigma} \cdot \begin{pmatrix} \ln x_1 \\ \ln x_2 \\ \ln x_3 \\ \ln x_4 \end{pmatrix}
$$

$$
= \begin{pmatrix} 1 \\ 1 \\ 1 \\ 1 \end{pmatrix} \cdot \begin{pmatrix} \ln x_1 \\ \ln x_2 \\ \ln x_3 \\ \ln x_4 \end{pmatrix} \cdot \begin{pmatrix} -\frac{\mu}{\sigma} \\ \frac{1}{\sigma} \end{pmatrix}
$$

$$
\Rightarrow \Phi^{-1}(\pi_s) = X_1 \cdot \begin{pmatrix} -\frac{\mu}{\sigma} \\ \frac{1}{\sigma} \end{pmatrix}
$$

(3.4.17)

(3.4.18)

where

$$
x_1 = \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ \cdots \\ x_{k-1} \end{pmatrix}
$$

$$
x_2 = \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ \cdots \\ x_{k-2} \end{pmatrix}
$$

$$
x_3 = \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ \cdots \\ x_{k-3} \end{pmatrix}
$$

$$
x_4 = \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ \cdots \\ x_{k-4} \end{pmatrix}
$$

Equation 3.4.18 is a linear model in the parameters $-\frac{\mu}{\sigma}$ and $\frac{1}{\sigma}$.

Equation 3.3.35 is equivalent to

$$
\left( I - X_1(X_1'X_1)^{-1}X_1' \right) \cdot \Phi^{-1}(\pi_s) = 0
$$
\[
C \cdot \Phi^{-1}(\pi_S) = 0 \\
g(\pi) = 0
\]

\(\pi_S\) is the projection matrix orthogonal to the columns of the design matrix \(X_1\). Note that \(CX_1 = 0\).

The function \(g(\pi) = 0\) satisfies the conditions of Proposition 1 and the estimation algorithm can be used to estimate the parameters \(\mu\) and \(\sigma^2\) of the lognormal distribution.

To summarize, the constraints imposed by the lognormal distribution are specified by

\[
g(\pi) = C \cdot \Phi^{-1}(\pi_S) = C \cdot \Phi^{-1}(S \cdot \pi) = 0
\]

with

\[
C = I - X_1(X_1'X_1)^{-1}X_1'.
\]

The derivative of \(g(\pi)\) with respect to \(\pi\) is

\[
G_\pi = \frac{\partial g(\pi)}{\partial \pi} = C \cdot \frac{\partial}{\partial \pi} \Phi^{-1}(S \cdot \pi) \cdot S
\]

that is equal to

\[
G_\pi = C \cdot \begin{bmatrix}
\frac{1}{\phi \left( \frac{\ln x - \mu \cdot 1}{\sigma} \right)} \\
\text{diag}\left\{ \phi \left( \frac{\ln x - \mu \cdot 1}{\sigma} \right) \right\}
\end{bmatrix} S.
\]

The matrix \(S\) to be used is the same matrix as defined at the fitting of the Weibull or the log-logistic model.

Since \(G_\pi\) depends on \(\mu\) and \(\sigma\) in the iterative procedure, these parameters will be estimated within the iterative stages and the final estimates will be obtained on convergence.

The SAS/IML program to fit a lognormal model to grouped survival data with staggered entry of policies appears in Appendix A.

3.4.6 Fitting of four survival distributions to the four histograms

Fitting of four Weibull distributions

Four Weibull distributions are to be fitted to the four histograms.
Consider four Weibull distributions with parameters \((\lambda_1, \alpha_1)\), \((\lambda_2, \alpha_2)\), \((\lambda_3, \alpha_3)\) and \((\lambda_4, \alpha_4)\) respectively.

Maximum likelihood estimation of the parameters is done subject to constraints imposed by the four Weibull distributions and further constraints that the \(\lambda_i\)'s are equal and \(\alpha_i\)'s are equal.

The four Weibull models under constraints \(\pi_{S1}, \pi_{S2}, \pi_{S3}, \pi_{S4}\), can be written from Equation 3.3.14 as follows:

\[
\begin{pmatrix}
\ln \left\{ -\ln(1 - \pi_{S1}) \right\} \\
\ln \left\{ -\ln(1 - \pi_{S2}) \right\} \\
\ln \left\{ -\ln(1 - \pi_{S3}) \right\} \\
\ln \left\{ -\ln(1 - \pi_{S4}) \right\}
\end{pmatrix}
= \begin{pmatrix}
1 & \ln x_1 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 1 & \ln x_2 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 1 & \ln x_3 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 1 & \ln x_4
\end{pmatrix} \cdot \begin{pmatrix}
\ln \lambda_1 \\
\alpha_1 \\
\ln \lambda_2 \\
\alpha_2 \\
\ln \lambda_3 \\
\alpha_3 \\
\ln \lambda_4 \\
\alpha_4
\end{pmatrix}
\]

(3.4.23)

where

\[
x_1 = \begin{pmatrix}
x_1 \\
x_2 \\
x_3 \\
\vdots \\
x_{k-1}
\end{pmatrix} \quad x_2 = \begin{pmatrix}
x_1 \\
x_2 \\
x_3 \\
\vdots \\
x_{k-2}
\end{pmatrix} \quad x_3 = \begin{pmatrix}
x_1 \\
x_2 \\
x_3 \\
\vdots \\
x_{k-3}
\end{pmatrix} \quad \text{and} \quad x_4 = \begin{pmatrix}
x_1 \\
x_2 \\
x_3 \\
\vdots \\
x_{k-4}
\end{pmatrix}
\]

Equation 3.4.23 is a **linear model** in the parameters \(\ln \lambda_1, \alpha_1, \ln \lambda_2, \alpha_2, \ln \lambda_3, \alpha_3, \ln \lambda_4\) and \(\alpha_4\).

Maximum likelihood estimation of these parameters subject to further constraints that the \(\lambda_i\)'s are equal and the \(\alpha_i\)'s are equal can be done similar to the fitting of one Weibull to the four histograms, when the following changes are made.

From Equation 3.4.23 follows that the design matrix for the fitting of four Weibull distri-
butions is
\[
X_1 = \begin{pmatrix}
1 & \ln x_1 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 1 & \ln x_2 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 1 & \ln x_3 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 1 & \ln x_4
\end{pmatrix}.
\]

The four Weibull models in Equation 3.4.23 are equivalent to
\[
(I - X_1 (X_1' X_1)^{-1} X_1') \cdot \begin{pmatrix}
\ln \{-\ln(1 - \pi_{S1})\} \\
\ln \{-\ln(1 - \pi_{S2})\} \\
\ln \{-\ln(1 - \pi_{S3})\} \\
\ln \{-\ln(1 - \pi_{S4})\}
\end{pmatrix} = 0
\]
\[
C' \cdot \begin{pmatrix}
\ln \{-\ln(1 - \pi_{S1})\} \\
\ln \{-\ln(1 - \pi_{S2})\} \\
\ln \{-\ln(1 - \pi_{S3})\} \\
\ln \{-\ln(1 - \pi_{S4})\}
\end{pmatrix} = 0
\]
\[
g(\pi) = 0
\]

\(C\) is the projection matrix orthogonal to the columns of the design matrix \(X_1\). Note that \(CX_1 = 0\).

The constraints that the \(\lambda_i\)'s are equal and the \(\alpha_i\)'s are equal are specified by
\[
H \cdot \begin{pmatrix}
\ln \lambda_1 \\
\alpha_1 \\
\ln \lambda_2 \\
\alpha_2 \\
\ln \lambda_3 \\
\alpha_3 \\
\ln \lambda_4 \\
\alpha_4
\end{pmatrix} = 0 \quad (3.4.24)
\]

where
\[
H = \begin{pmatrix}
1 & 0 & -1 & 0 & 0 & 0 & 0 & 0 \\
1 & 0 & 0 & 0 & -1 & 0 & 0 & 0 \\
1 & 0 & 0 & 0 & 0 & -1 & 0 & 0 \\
0 & 1 & 0 & -1 & 0 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 & -1 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 & 0 & -1 & 0 & 0 \\
0 & 1 & 0 & 0 & 0 & 0 & -1 & 0
\end{pmatrix}.
\]
Equation 3.4.24 is equivalent to

\[
\begin{pmatrix}
\ln \lambda_1 \\
\alpha_1 \\
\ln \lambda_2 \\
\alpha_2 \\
\ln \lambda_3 \\
\alpha_3 \\
\ln \lambda_4 \\
\alpha_4
\end{pmatrix} = (X_1'X_1)^{-1}X_1' \cdot \begin{pmatrix}
\ln \{-\ln(1-\pi_{S1})\} \\
\ln \{-\ln(1-\pi_{S2})\} \\
\ln \{-\ln(1-\pi_{S3})\} \\
\ln \{-\ln(1-\pi_{S4})\}
\end{pmatrix}
\] (3.4.25)

that is

\[
H \cdot \begin{pmatrix}
\ln \lambda_1 \\
\alpha_1 \\
\ln \lambda_2 \\
\alpha_2 \\
\ln \lambda_3 \\
\alpha_3 \\
\ln \lambda_4 \\
\alpha_4
\end{pmatrix} = H \cdot (X_1'X_1)^{-1}X_1' \cdot \begin{pmatrix}
\ln \{-\ln(1-\pi_{S1})\} \\
\ln \{-\ln(1-\pi_{S2})\} \\
\ln \{-\ln(1-\pi_{S3})\} \\
\ln \{-\ln(1-\pi_{S4})\}
\end{pmatrix}
\]

or

\[
0 = D \cdot \begin{pmatrix}
\ln \{-\ln(1-\pi_{S1})\} \\
\ln \{-\ln(1-\pi_{S2})\} \\
\ln \{-\ln(1-\pi_{S3})\} \\
\ln \{-\ln(1-\pi_{S4})\}
\end{pmatrix}
\] (3.4.26)

Equation 3.4.26 specifies the further constraints of equal parameters for the four histograms.

In the notation for staggered entry of policies, as described in Table 3.2 with four entry periods and k, the number of class intervals, equal to seven, matrix D is a 6 x 18 matrix.

A new matrix is formed that takes the further constraints into account. This matrix is created by concatenating the six rows of D to the 18 rows of C. This new matrix is then used instead of the matrix C in further calculations.

**Fitting of four log-logistic distributions**

Four log-logistic distributions are to be fitted to the four histograms.
Consider four log-logistic distributions with parameters $(\lambda_1, \alpha_1)$, $(\lambda_2, \alpha_2)$, $(\lambda_3, \alpha_3)$ and $(\lambda_4, \alpha_4)$ respectively.

Maximum likelihood estimation of the parameters is done subject to constraints imposed by the four log-logistic distributions and further constraints that the $\lambda_i$'s are equal and $\alpha_i$'s are equal.

The four log-logistic models under constraints $\pi_{S1}$, $\pi_{S2}$, $\pi_{S3}$, $\pi_{S4}$, can be written from Equation 3.3 .24 as follows:

$$
\begin{pmatrix}
\ln \left\{ \pi_{S1} \right\} - \ln \left\{ 1 - \pi_{S1} \right\} \\
\ln \left\{ \pi_{S2} \right\} - \ln \left\{ 1 - \pi_{S2} \right\} \\
\ln \left\{ \pi_{S3} \right\} - \ln \left\{ 1 - \pi_{S3} \right\} \\
\ln \left\{ \pi_{S4} \right\} - \ln \left\{ 1 - \pi_{S4} \right\}
\end{pmatrix} =
\begin{pmatrix}
1 & \ln x_1 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 1 & \ln x_2 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 1 & \ln x_3 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 1 & \ln x_4 & 0
\end{pmatrix}
\begin{pmatrix}
\ln \lambda_1 \\
\alpha_1 \\
\ln \lambda_2 \\
\alpha_2 \\
\ln \lambda_3 \\
\alpha_3 \\
\ln \lambda_4 \\
\alpha_4
\end{pmatrix}

(3.4 .27)

where

$$
\begin{pmatrix}
x_1 \\
x_2 \\
x_3 \\
\vdots \\
x_{k-1}
\end{pmatrix}
= 
\begin{pmatrix}
x_1 \\
x_2 \\
x_3 \\
\vdots \\
x_{k-2}
\end{pmatrix}
= 
\begin{pmatrix}
x_1 \\
x_2 \\
x_3 \\
\vdots \\
x_{k-3}
\end{pmatrix}
= 
\begin{pmatrix}
x_1 \\
x_2 \\
x_3 \\
\vdots \\
x_{k-4}
\end{pmatrix}
$$

Equation 3.4 .27 is a linear model in the parameters $\ln \lambda_1, \alpha_1, \ln \lambda_2, \alpha_2, \ln \lambda_3, \alpha_3, \ln \lambda_4$ and $\alpha_4$.

Maximum likelihood estimation of these parameters subject to further constraints that the $\lambda_i$'s are equal and the $\alpha_i$'s are equal can be done similar to the fitting of one log-logistic to the four histograms, when the following changes are made.

From Equation 3.4 .27 follows that the design matrix for the fitting of four log-logistic
distributions is
\[
X_1 = \begin{pmatrix}
1 & \ln x_1 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 1 & \ln x_2 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 1 & \ln x_3 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 1 & \ln x_4
\end{pmatrix}.
\]

The four log-logistic models in Equation 3.4 .27 are equivalent to

\[
\left(I - X_1(X_1'X_1)^{-1}X_1'\right) \cdot \begin{pmatrix}
\ln \{\pi_{S1}\} - \ln \{1 - \pi_{S1}\} \\
\ln \{\pi_{S2}\} - \ln \{1 - \pi_{S2}\} \\
\ln \{\pi_{S3}\} - \ln \{1 - \pi_{S3}\} \\
\ln \{\pi_{S4}\} - \ln \{1 - \pi_{S4}\}
\end{pmatrix} = 0
\]

\[
C \cdot \begin{pmatrix}
\ln \{\pi_{S1}\} - \ln \{1 - \pi_{S1}\} \\
\ln \{\pi_{S2}\} - \ln \{1 - \pi_{S2}\} \\
\ln \{\pi_{S3}\} - \ln \{1 - \pi_{S3}\} \\
\ln \{\pi_{S4}\} - \ln \{1 - \pi_{S4}\}
\end{pmatrix} = 0
\]

\[
g(\pi) = 0
\]

\(C\) is the projection matrix orthogonal to the columns of the design matrix \(X_1\). Note that \(CX_1 = 0\).

The constraints that the \(\lambda_i\)'s are equal and the \(\alpha_i\)'s are equal are specified by

\[
H \cdot \begin{pmatrix}
\ln \lambda_1 \\
\alpha_1 \\
\ln \lambda_2 \\
\alpha_2 \\
\ln \lambda_3 \\
\alpha_3 \\
\ln \lambda_4 \\
\alpha_4
\end{pmatrix} = 0
\]

(3.4 .28)

where

\[
H = \begin{pmatrix}
1 & 0 & -1 & 0 & 0 & 0 & 0 & 0 \\
1 & 0 & 0 & -1 & 0 & 0 & 0 & 0 \\
1 & 0 & 0 & 0 & 0 & -1 & 0 & 0 \\
0 & 1 & 0 & -1 & 0 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 & 0 & -1 & 0 & 0 \\
0 & 1 & 0 & 0 & 0 & 0 & -1 & 0 \\
0 & 1 & 0 & 0 & 0 & 0 & 0 & -1
\end{pmatrix}.
\]
Equation 3.4 .28 is equivalent to

\[
\begin{pmatrix}
\ln \lambda_1 \\
\alpha_1 \\
\ln \lambda_2 \\
\alpha_2 \\
\ln \lambda_3 \\
\alpha_3 \\
\ln \lambda_4 \\
\alpha_4 \\
\end{pmatrix}
= (X_1'X_1)^{-1}X_1'
\cdot
\begin{pmatrix}
\ln \{\pi_{S1}\} - \ln \{1 - \pi_{S1}\} \\
\ln \{\pi_{S2}\} - \ln \{1 - \pi_{S2}\} \\
\ln \{\pi_{S3}\} - \ln \{1 - \pi_{S3}\} \\
\ln \{\pi_{S4}\} - \ln \{1 - \pi_{S4}\} \\
\end{pmatrix}
\]

(3.4 .29)

that is

\[
\begin{pmatrix}
\ln \lambda_1 \\
\alpha_1 \\
\ln \lambda_2 \\
\alpha_2 \\
\ln \lambda_3 \\
\alpha_3 \\
\ln \lambda_4 \\
\alpha_4 \\
\end{pmatrix}
= H \cdot (X_1'X_1)^{-1}X_1'
\cdot
\begin{pmatrix}
\ln \{\pi_{S1}\} - \ln \{1 - \pi_{S1}\} \\
\ln \{\pi_{S2}\} - \ln \{1 - \pi_{S2}\} \\
\ln \{\pi_{S3}\} - \ln \{1 - \pi_{S3}\} \\
\ln \{\pi_{S4}\} - \ln \{1 - \pi_{S4}\} \\
\end{pmatrix}
\]

or

\[
0 = D
\cdot
\begin{pmatrix}
\ln \{\pi_{S1}\} - \ln \{1 - \pi_{S1}\} \\
\ln \{\pi_{S2}\} - \ln \{1 - \pi_{S2}\} \\
\ln \{\pi_{S3}\} - \ln \{1 - \pi_{S3}\} \\
\ln \{\pi_{S4}\} - \ln \{1 - \pi_{S4}\} \\
\end{pmatrix}
\]

(3.4 .30)

Equation 3.4 .30 specifies the further constraints of equal parameters for the four histograms.

If k, the number of class intervals, is equal to seven, then matrix D is a 6 x 18 matrix.

A new matrix is formed that takes the further constraints into account. This matrix is created by concatenating the six rows of D to the 18 rows of C. This new matrix is then used instead of the matrix C in further calculations.

Fitting of four lognormal distributions

Four lognormal distributions are to be fitted to the four histograms.
Consider four lognormal distributions with parameters \((\mu_1, \sigma_1^2)\), \((\mu_2, \sigma_2^2)\), \((\mu_3, \sigma_3^2)\) and \((\mu_4, \sigma_4^2)\) respectively.

Maximum likelihood estimation of the parameters is done subject to constraints imposed by the four lognormal distributions and further constraints that the \(\mu_i\)'s are equal and \(\sigma_i\)'s are equal.

The four lognormal models under constraints \(\pi_{S1}, \pi_{S2}, \pi_{S3}, \pi_{S4}\), can be written from Equation 3.3 – 3.5 as follows:

\[
\begin{pmatrix}
\ln \{\Phi^{-1}(\pi_{S1})\} \\
\ln \{\Phi^{-1}(\pi_{S2})\} \\
\ln \{\Phi^{-1}(\pi_{S3})\} \\
\ln \{\Phi^{-1}(\pi_{S4})\}
\end{pmatrix}
=
\begin{pmatrix}
1 & \ln x_1 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 1 & \ln x_2 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 1 & \ln x_3 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 1 & \ln x_4
\end{pmatrix}
\begin{pmatrix}
-\frac{\mu_1}{\sigma_1} \\
-\frac{\mu_2}{\sigma_2} \\
-\frac{\mu_3}{\sigma_3} \\
-\frac{\mu_4}{\sigma_4}
\end{pmatrix}
\tag{3.4 .31}
\]

where

\[
x_1 = \\
x_2 = \\
x_3 = \\
x_4 = \\
\begin{pmatrix}
x_1 \\
x_2 \\
x_3 \\
\cdots \\
x_{k-1}
\end{pmatrix} = \\
\begin{pmatrix}
x_1 \\
x_2 \\
x_3 \\
\cdots \\
x_{k-1}
\end{pmatrix} = \\
\begin{pmatrix}
x_1 \\
x_2 \\
x_3 \\
\cdots \\
x_{k-3}
\end{pmatrix} \quad \text{and} \quad \\
\begin{pmatrix}
x_1 \\
x_2 \\
x_3 \\
\cdots \\
x_{k-4}
\end{pmatrix}
\]

Equation 3.4 .31 is a linear model in the parameters \(\mu_1, \sigma_1^2, \mu_2, \sigma_2^2, \mu_3, \sigma_3^2, \mu_4 \text{ and } \sigma_4^2\).

Maximum likelihood estimation of these parameters subject to further constraints that the \(\mu_i\)'s are equal and the \(\sigma_i\)'s are equal can be done similar to the fitting of one lognormal to the four histograms, when the following changes are made.

From Equation 3.4 .31 follows that the design matrix for the fitting of four lognormal
The four lognormal models in Equation 3.4 .31 are equivalent to

\[
\begin{align*}
\left( I - X_1(X_1'X_1)^{-1}X_1' \right) \cdot \\
\begin{pmatrix}
\ln \{ \Phi^{-1}(\pi_{s1}) \} \\
\ln \{ \Phi^{-1}(\pi_{s2}) \} \\
\ln \{ \Phi^{-1}(\pi_{s3}) \} \\
\ln \{ \Phi^{-1}(\pi_{s4}) \}
\end{pmatrix} &= 0 \\
\begin{pmatrix}
\ln \{ \Phi^{-1}(\pi_{s1}) \} \\
\ln \{ \Phi^{-1}(\pi_{s2}) \} \\
\ln \{ \Phi^{-1}(\pi_{s3}) \} \\
\ln \{ \Phi^{-1}(\pi_{s4}) \}
\end{pmatrix} &= 0 \\
g(\pi) &= 0
\end{align*}
\]

\( C \) is the projection matrix orthogonal to the columns of the design matrix \( X_1 \). Note that \( CX_1 = 0 \).

The constraints that the \( \mu_i \)'s are equal and the \( \sigma_i \)'s are equal are specified by

\[
H \cdot \begin{pmatrix}
\frac{\mu_1}{\sigma_1} \\
\frac{1}{\sigma_1} \\
\frac{\mu_2}{\sigma_2} \\
\frac{1}{\sigma_2} \\
\frac{\mu_3}{\sigma_3} \\
\frac{1}{\sigma_3} \\
\frac{\mu_4}{\sigma_4} \\
\frac{1}{\sigma_4}
\end{pmatrix} = 0
\]

where

\[
H = \begin{pmatrix}
1 & 0 & -1 & 0 & 0 & 0 & 0 & 0 \\
1 & 0 & 0 & -1 & 0 & 0 & 0 & 0 \\
1 & 0 & 0 & 0 & 0 & -1 & 0 & 0 \\
0 & 1 & 0 & -1 & 0 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 & -1 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 & 0 & -1 & 0 & 0 \\
0 & 1 & 0 & 0 & 0 & 0 & 0 & -1
\end{pmatrix}
\]
Equation 3.4.32 is equivalent to

\[
\begin{pmatrix}
-\frac{\bar{y}_1}{c_1} \\
\frac{1}{\sigma_1} \\
-\frac{\bar{y}_2}{c_2} \\
\frac{1}{\sigma_2} \\
-\frac{\bar{y}_3}{c_3} \\
\frac{1}{\sigma_3} \\
-\frac{\bar{y}_4}{c_4} \\
\frac{1}{\sigma_4}
\end{pmatrix}
= (X_1'X_1)^{-1}X_1' \cdot \begin{pmatrix}
\ln \{ \Phi^{-1}(\pi_{S1}) \} \\
\ln \{ \Phi^{-1}(\pi_{S2}) \} \\
\ln \{ \Phi^{-1}(\pi_{S3}) \} \\
\ln \{ \Phi^{-1}(\pi_{S4}) \}
\end{pmatrix}
\]  
\tag{3.4.33}

That is

\[
H = (X_1'X_1)^{-1}X_1' \cdot \begin{pmatrix}
\ln \{ \Phi^{-1}(\pi_{S1}) \} \\
\ln \{ \Phi^{-1}(\pi_{S2}) \} \\
\ln \{ \Phi^{-1}(\pi_{S3}) \} \\
\ln \{ \Phi^{-1}(\pi_{S4}) \}
\end{pmatrix}
\]

or

\[
0 = D \cdot \begin{pmatrix}
\ln \{ \Phi^{-1}(\pi_{S1}) \} \\
\ln \{ \Phi^{-1}(\pi_{S2}) \} \\
\ln \{ \Phi^{-1}(\pi_{S3}) \} \\
\ln \{ \Phi^{-1}(\pi_{S4}) \}
\end{pmatrix}
\]  
\tag{3.4.34}

Equation 3.4.34 specifies the further constraints of equal parameters for the four histograms.

If \( k \), the number of class intervals, is equal to seven, then matrix \( D \) is a \( 6 \times 18 \) matrix.

A new matrix is formed that takes the further constraints into account. This matrix is created by concatenating the six rows of \( D \) to the 18 rows of \( C \). This new matrix is then used instead of the matrix \( C \) in further calculations.

### 3.4.7 Fitting of a joint histogram to the four histograms

A joint histogram is to be fitted to the four histograms of the four relative frequency distributions under constraints imposed by the experimental design.
These constraints in matrix form are \( G \cdot \pi = 0 \) with \( \pi' = (\pi_1', \pi_2', \pi_3', \pi_4') \) where

\[
\begin{align*}
\pi_1 &= (\pi_{1,1}, \pi_{1,2}, \pi_{1,3}, \ldots, \pi_{1,k})' \text{ is a } k \times 1 \text{ probability vector} \\
\pi_2 &= (\pi_{2,1}, \pi_{2,2}, \pi_{2,3}, \ldots, \pi_{2,k-1})' \text{ is a } (k - 1) \times 1 \text{ probability vector} \\
\pi_3 &= (\pi_{3,1}, \pi_{3,2}, \pi_{3,3}, \ldots, \pi_{3,k-2})' \text{ is a } (k - 2) \times 1 \text{ probability vector} \\
\pi_4 &= (\pi_{4,1}, \pi_{4,2}, \pi_{4,3}, \ldots, \pi_{4,k-3})' \text{ is a } (k - 3) \times 1 \text{ probability vector} \\
\end{align*}
\]

and

\[
G = \begin{pmatrix}
I & 0 & 0 & 0 & -I & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
I & 0 & 0 & 0 & 0 & 0 & 0 & -I & 0 & 0 & 0 & 0 \\
I & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & -I & 0 \\
0' & 1 & 1 & 1 & 1 & 0' & -1 & -1 & -1 & 0' & 0 & 0 & 0' \\
0' & 1 & 1 & 1 & 1 & 0' & 0 & 0 & 0 & 0' & -1 & -1 & 0' \\
0' & 1 & 1 & 1 & 1 & 0' & 0 & 0 & 0 & 0' & 0 & 0 & 0' -1 \\
0' & 0 & 1 & 0 & 0 & 0' & 0 & -1 & 0 & 0' & 0 & 0 & 0' \\
0' & 1 & 0 & 0 & 0 & 0' & -1 & 0 & 0 & 0' & 0 & 0 & 0' \\
\end{pmatrix}
\]

The function \( g(\pi) = 0 \) satisfies the conditions of Proposition 1 and the estimation algorithm can be used to estimate the relative frequencies of the joint relative frequency distribution.

Note that the constraints \( G \cdot \pi = g(\pi) \) is a linear function of \( \pi \). This implies that \( G = \frac{\partial g(\pi)}{\partial \pi} \) and only a single iteration is needed in the iterative procedure to determine the MLE of \( \pi \) under the constraints \( g(\pi) = 0 \).

This MLE of \( \pi \) is

\[
\hat{\pi}_c = p - (GV)' (GVG')^* g(p)
\]

with asymptotic variance-covariance matrix

\[
cov(\hat{\pi}_c) = V - (GV)' (GVG')^* GV.
\]

The variance-covariance matrix \( V \) to be used is the estimated variance-covariance matrix of the multinomial distribution for each entry period.

\[
\implies V = \text{block}(\hat{V}_1, \hat{V}_2, \hat{V}_3, \hat{V}_4)
\]

and

\[
\hat{V}_i = \frac{1}{n_i} [\text{diag}(p_i) - p_i p_i'] \quad i = 1, 2, 3, 4
\]

Once the iterative procedure has converged, the estimated joint relative frequencies can be
read off from the estimated vector of probabilities $\hat{\pi}_c$. The histogram of the fitted joint relative frequency distribution is a representative image of the four histograms.

The SAS/IML program to fit a joint histogram to the four histograms of the entry groups appears in Appendix A.

3.4.8 **Estimated survivor and hazard functions and percentiles**

Once the parameters of the Weibull and log-logistic survival distributions have been estimated, estimated hazard and survivor functions and the odds of a lapse can be calculated for time $t$. Percentiles of these survival distributions can also be estimated.
Survival distribution

Weibull

Estimated hazard function
\[ \hat{h}(t) = \hat{\lambda} \cdot \hat{\alpha} \cdot t^{\hat{\alpha} - 1} \]

Estimated survivor function
\[ \hat{S}(t) = \exp(-\hat{\lambda} \cdot t^{\hat{\alpha}}) \]

Estimated odds of a lapse
\[ \hat{\text{odds}}(t) = \frac{1 - \hat{S}(t)}{\hat{S}(t)} = \exp(\hat{\lambda} \cdot t^{\hat{\alpha} - 1}) \]

Estimated percentiles
\[ \hat{t}_p = \left( \frac{\ln \frac{100}{100 - p}}{\hat{\lambda}} \right) \frac{1}{\hat{\alpha}} \]

Log-logistic

Estimated hazard function
\[ \hat{h}(t) = \frac{\hat{\lambda} \cdot \hat{\alpha} \cdot t^{\hat{\alpha} - 1}}{1 + \hat{\lambda} \cdot t^{\hat{\alpha}}} \]

Estimated survivor function
\[ \hat{S}(t) = \frac{1}{1 + \hat{\lambda} \cdot t^{\hat{\alpha}}} \]

Estimated odds of a lapse
\[ \hat{\text{odds}}(t) = \frac{1 - \hat{S}(t)}{\hat{S}(t)} = \hat{\lambda} \cdot t^{\hat{\alpha}} \]

Estimated percentiles
\[ \hat{t}_p = \left( \frac{\ln \frac{p}{100 - p}}{\hat{\lambda}} \right) \frac{1}{\hat{\alpha}} \]
3.5 Simulation Studies

Simulations are used to compare the maximum likelihood estimation under constraints procedure with the standard maximum likelihood estimation procedure that is used by SAS.

A thousand sets of right-censored data with a fixed censoring time are simulated from each of three survival distributions, namely the Weibull, the log-logistic and the lognormal distributions. The percentage censoring is about 35% and censoring at continuous data as well as censoring at grouped data, the special case of interval-censored data, are considered.

For the continuous case, three groups of 20, 50, 100 and 200 observations are generated from each of three survival distributions, with different scale and shape parameters for the three groups. A scale parameter of \( \lambda = 0.15 \) and a shape parameter of \( \alpha = 0.5 \) are selected for the first group generated from the Weibull(\( \lambda, \alpha \)) and the log-logistic(\( \lambda, \alpha \)) distributions, while a \( \mu \)-value of 2 and a \( \sigma \)-value of 0.5 are used for the generation from the lognormal(\( \mu, \sigma \)) distribution. The second and third groups use extreme \( \lambda \)-values of 10 and 30 and extreme \( \alpha \)-values of 3 and 1.8 for generation from the Weibull and log-logistic distributions and \( \mu \)-values of 5 and 3 and \( \sigma \)-values of 0.2 and 0.03 for generation from the lognormal distribution. In order to be able to apply the IML program for maximum likelihood estimation subject to constraints, the continuous data are grouped into intervals with boundaries the means of two adjacent observed survival times with frequency 1 in each interval. The frequency of the last open interval is equal to the number of censored survival times. The standard method of maximum likelihood estimation used by PROC LIFEREG of SAS is applied to the continuous data without grouping into such intervals.

For the grouped data case, three groups of 100 observations (grouped into five intervals), 200 observations (grouped into five intervals), 2000 observations (grouped into five intervals) and 2000 observations (grouped into ten intervals) are generated from each of the three survival distributions, with parameters similar to the continuous case.

Programs to generate lifetime data and to run simulations with the technique of maximum likelihood estimation under constraints, appear in Appendix A. Maximum likelihood estimates by the standard method are also found using PROC LIFEREG of SAS. For comparison purposes, both estimation techniques are performed on the same set of simulated data in the same program. The means of the thousand simulated \( \hat{\lambda} \)- and \( \hat{\alpha} \)-values are computed as maximum likelihood estimators of the model parameters \( \lambda \) and \( \alpha \).
These estimators of the model parameters are considered to be significantly biased if the absolute difference between the model parameter and the estimator is greater than three standard errors of the mean. This criterion can be motivated as follows. For large sample sizes, the sampling distribution of the mean is approximately normally distributed and then the probability that the absolute difference between the model parameter and the estimator will lie within three standard errors of the mean, is 0.9999. For small sample sizes (not assuming normality) the inequality of Chebyshev specifies that this probability is at least 0.8889. Thus the confidence coefficient in this case will be between 0.8889 and 0.9999. A significantly biased estimator over-estimates the model parameter if its value is more than three standard errors of the mean to the right of the model parameter, and is an under-estimator if its value is more than three standard errors of the mean to the left of the model parameter.

Table 3.3 represents the simulation results for the continuous case for samples of various sizes when generating from a Weibull model.

Table 3.4 represents the simulation results for the grouped data case for samples of various sizes, classified in five or ten intervals, when generating from a Weibull model.

Table 3.5 represents the simulation results for the continuous case for samples of various sizes when generating from a log-logistic model.

Table 3.6 represents the simulation results for the grouped data case for samples of various sizes, classified in five or ten intervals, when generating from a log-logistic model.

Table 3.7 represents the simulation results for the continuous case for samples of various sizes when generating from a lognormal model.

Table 3.8 represents the simulation results for the grouped data case for samples of various sizes, classified in five or ten intervals, when generating from a lognormal model.

For generation from the Weibull and log-logistic distributions, the maximum likelihood estimates of the IML method compare very well to the maximum likelihood estimates of the SAS method. The biasness of these estimates is very small for values of $\lambda$ and $\alpha$ that are usually used in practice, namely $\lambda=0.15$ and $\alpha=0.5$. For larger values of $\lambda$ and $\alpha$, the model parameters seem to be overestimated. The biasness of the estimates reduces when the sample size increases, as can be expected from maximum likelihood estimates which are asymptotically unbiased. The same conclusions can be made for generation from the lognormal distribution.

Chapter 4

PARAMETRIC REGRESSION MODELS FOR SURVIVAL DATA WITH COVARIATES

4.1 Notation

Suppose that the distribution of $T$ depends on a vector of fixed-time explanatory variables (covariates) $Z = (Z_1, Z_2, ..., Z_p)'$. The right-censored survival data set then consists of triples $(T_j, \delta_j, Z_j)$ $j = 1, 2, ..., n$ where

- $T_j =$ lifetime for the $j^{th}$ policy
- $\delta_j =$ lapse indicator for the $j^{th}$ policy = \begin{cases} 1 & \text{if policy has lapsed} \\ 0 & \text{if lifetime is right-censored} \end{cases}$
- $Z_j = (Z_{j1}, Z_{j2}, ..., Z_{jp})'$ is the vector of explanatory variables for the $j^{th}$ policy at a fixed time

4.2 Three Approaches to Regression Modelling

The effect of covariates (risk factors on the lapse of policies) must be modelled in order to predict lifetimes of policies.

Either the conditional survivor function or the conditional hazard function can be modelled as a function of $p$ fixed covariates or risk factors $Z = (Z_1, Z_2, ..., Z_p)'$. 

87
Three general approaches to regression modelling of survival data will be discussed.

- **Accelerated Failure Time Model (AFM)**

  This model states that the **survivor function** at time $t$ of a policy with covariate $Z$ is the same as the survivor function of a policy with a baseline survivor function at a time $t \cdot \exp(\theta'Z)$ where $\theta = (\theta_1, \theta_2, ..., \theta_p)'$ is a vector of regression coefficients.

- **Proportional Hazards Model (PHM)**

  This model states that the **relative hazard rate** or **hazard rate** of a lapse at time $t$ of a policy, with risk vector $Z$, compared to a policy with the baseline characteristics (that means $Z = 0$), is a constant $e^{\beta'Z}$ where $\beta = (\beta_1, \beta_2, ..., \beta_p)'$ is a vector of regression coefficients.

- **Proportional Odds Model (POM)**

  This model states that the **relative odds** or **odds ratio** of a lapse at time $t$ of a policy, with risk vector $Z$, compared to a policy with the baseline characteristics (that means $Z = 0$), is a constant $e^{\beta'Z}$ where $\beta = (\beta_1, \beta_2, ..., \beta_p)'$ is a vector of regression coefficients.

The effect of the covariates in all three models is to **alter the scale parameter**, while the **shape parameter remains constant**.

Parametric regression models are discussed by [9, 7, 13, 16, 24, 26, 35]. A comparison between the AFM and the PHM is done by [21, 18], while [18] also compare the AFM and POM. The Weibull AFM and Weibull PHM are compared by [5], and [5] also compares the log-logistic AFM and the log-logistic POM.

The properties of the different models are compared in the following tables.
PARAMETRIC REGRESSION MODELS

ACCELERATED FAILURE TIME MODEL

models the 

**survivor function**

of a policy

with risk vector

\[ Z = (Z_1, Z_2, ..., Z_p)' \]

and regression coefficients \( \theta = (\theta_1, \theta_2, ..., \theta_p)' \)

\[
S(t|Z) = S_0(e^{\theta'Zt})
\]

\( S(t|Z) \) is survivor function at time \( t \) for a policy with risk vector \( Z \)

\( S_0(t) \) is **baseline survivor function** at time \( t \) with a specified parametric form

( survivor function for a policy whose risk factors all take the value zero)

\[ \Rightarrow S_0(t) = S(t \mid Z = 0) \]

- effect of covariates is multiplicative on **survival time**
- \( e^{\theta'Z} = \exp\left\{ \sum_{k=1}^{p} \theta_k Z_k \right\} \) is **acceleration factor**
- \( e^{\theta_k Z_k} \) indicates how risk factor \( Z_k \) "speeds up" or "slows down" the lifetime of a policy
- median lifetime for a given \( Z \) is equal to baseline median lifetime \( \times \) acceleration factor

\[
h(t|Z) = e^{\theta'Z} h_0(e^{\theta'Zt})
\]

\[
S(t|Z) = S_0(e^{\theta'Zt})
\]

PROPORTIONAL HAZARDS MODEL

models the 

**hazard rate**

of a lapse for a policy

with risk vector

\[ Z = (Z_1, Z_2, ..., Z_p)' \]

and regression coefficients \( \beta = (\beta_1, \beta_2, ..., \beta_p)' \)

\[
h(t|Z) = h_0(t)e^{\beta'Z}
\]

\( h(t|Z) \) is hazard rate of a lapse at time \( t \) for a policy with risk vector \( Z \)

\( h_0(t) \) is **baseline hazard rate** for a policy at time \( t \) with a specified parametric form

( hazard rate for a policy whose risk factors all take the value zero)

\[ \Rightarrow h_0(t) = h(t \mid Z = 0) \]

- effect of covariates is multiplicative on **hazard rate**
- \( e^{\beta'Z} = \exp\left\{ \sum_{k=1}^{p} \beta_k Z_k \right\} \) is **link function**
- \( e^{\beta_k Z_k} \) is **risk score** for risk factor \( Z_k \)
- \( k = 1, 2, ..., p \)
- If \( S_0(t) \) is unspecified, the PHM is the famous **semiparametric Cox's PHM**: [23]

\[
h(t|Z) = e^{\beta'Z} h_0(t)
\]

\[
S(t|Z) = [S_0(t)]e^{\beta'Z}
\]
Special case: lifetimes are assumed to have a $\text{Weibull}(\lambda, \alpha)$

**Weibull AFM**

\[ h_0(t) = \lambda \alpha t^{\alpha - 1} \]

From AFM: The hazard function of the $j^{th}$ policy with risk vector $Z$ is

\[
\begin{align*}
  h_j(t) &= e^{\theta' Z} \lambda \alpha \left( e^{\theta' Z} t \right)^{\alpha - 1} \\
  &= \left[ (e^{\theta' Z})^\alpha \lambda \right] \alpha t^{\alpha - 1} \\
  &= (e^{\theta' Z})^\alpha h_0(t)
\end{align*}
\]

Also $S_0(t) = \exp \{ -\lambda t^\alpha \}$

From AFM: The survivor function of the $j^{th}$ policy with risk vector $Z$ is

\[
\begin{align*}
  S_j(t) &= S_0(e^{\theta' Z} t) \\
  &= \exp \left\{ -\lambda (e^{\theta' Z} t)^\alpha \right\} \\
  &= \exp \left\{ -\left[ \lambda (e^{\theta' Z})^\alpha \right] . t^\alpha \right\}
\end{align*}
\]

⇒ The lifetime of the $j^{th}$ policy has a

$\text{Weibull}(\lambda (e^{\theta' Z})^\alpha, \alpha)$ distribution

Say that Weibull possesses the accelerated failure time property

**Weibull PHM**

\[ h_0(t) = \lambda \alpha t^{\alpha - 1} \]

From PHM, The hazard function of the $j^{th}$ policy with risk vector $Z$ is

\[
\begin{align*}
  h_j(t) &= e^{\beta' Z} \lambda \alpha t^{\alpha - 1} \\
  &= [e^{\beta' Z} \lambda] \alpha t^{\alpha - 1} \\
  &= e^{\beta' Z} h_0(t)
\end{align*}
\]

Also $S_0(t) = \exp \{ -\lambda t^\alpha \}$

From PHM: The survivor function of the $j^{th}$ policy with risk vector $Z$ is

\[
\begin{align*}
  S_j(t) &= \exp \{ -\lambda t^\alpha \} e^{\beta' Z} \\
  &= \exp \left\{ \{ e^{\beta' Z} \} . ( -\lambda t^\alpha ) \right\} \\
  &= \exp \left\{ -[ \lambda e^{\beta' Z} ] . t^\alpha \right\}
\end{align*}
\]

⇒ The lifetime of the $j^{th}$ policy has a

$\text{Weibull}(\lambda e^{\beta' Z}, \alpha)$ distribution

Say that Weibull possesses the proportional hazards property
PARAMETRIC REGRESSION MODELS (continued)

ACCELERATED FAILURE TIME MODEL

models the survivor function of a policy with risk vector \( Z = (Z_1, Z_2, ..., Z_p)' \) and regression coefficients \( \theta = (\theta_1, \theta_2, ..., \theta_p)' \)

\[
S(t|Z) = S_0(e^{\theta'Z_t})
\]

- effect of covariates is multiplicative on survival time
- median time to a lapse (with given \( Z \))
  \[
  = [\text{baseline median time to a lapse}] \cdot e^{\theta'Z}
  \]

PROPORTIONAL ODDS MODEL

models the odds of a lapse at time \( t \) for a policy with risk vector \( Z = (Z_1, Z_2, ..., Z_p)' \) and regression coefficients \( \beta = (\beta_1, \beta_2, ..., \beta_p)' \)

\[
\frac{1 - S(t|Z)}{S(t|Z)} = e^{\beta'Z} \cdot \frac{1 - S_0(t)}{S_0(t)}
\]

- effect of covariates is multiplicative on the odds of a lapse at time \( t \)
- \( e^{\beta_k Z_k} \) is index for covariate \( Z_k \)
  \[
  k = 1, 2, ..., p
  \]
- If \( S_0(t) \) is unspecified, the POM is the semiparametric Cox’s regression model that includes a time-dependent covariate to produce non-proportional hazards
  Refer to [25, 3].
Special case: lifetimes are assumed to have a log-logistic($\lambda, \alpha$)

**log-logistic AFM**

From AFM: $S_0(t) = \frac{1}{1 + \lambda t^\alpha}$

From AFM: The survivor function of the $j^{th}$ policy with risk vector $Z$ is

$$S_j(t) = S_0(e^{\theta'Z}t) = \frac{1}{1 + \lambda(e^{\theta'Z})^\alpha} \cdot \frac{1}{1 + [\lambda(e^{\theta'Z})^\alpha] \cdot t^\alpha}$$

⇒ The lifetime of the $j^{th}$ policy has a log-logistic($\lambda(e^{\theta'Z})^\alpha, \alpha$) distribution

Say that log-logistic possesses the accelerated failure time property

**log-logistic POM**

From $S_0(t) = \frac{1}{1 + \lambda t^\alpha}$ follows that the baseline odds of a lapse at time $t$ is

$$\frac{1 - S_0(t)}{S_0(t)} = \lambda t^\alpha$$

From POM: The odds of a lapse of the $j^{th}$ policy at time $t$ with risk vector $Z$ is

$$\frac{1 - S_j(t)}{S_j(t)} = e^{\beta'Z} \cdot \lambda t^\alpha = [\lambda e^{\beta'Z}] \cdot t^\alpha$$

⇒ The lifetime of the $j^{th}$ policy has a log-logistic($\lambda e^{\beta'Z}, \alpha$) distribution

Say that log-logistic possesses the proportional odds property
4.3 Comparison between the AFM and the PHM

- The Weibull is the only continuous distribution which has the property of being both an AFM and a PHM.
  
The lifetimes under AFM $\sim$ Weibull($\lambda(e^{\theta'Z})^\alpha, \alpha$).
  
The lifetimes under PHM $\sim$ Weibull($\lambda e^{\beta'Z}, \alpha$).

- There is a direct correspondence between the parameters of the Weibull under these two models. It follows that when the $\beta_k$'s in the linear component of the PHM are divided by $\alpha$, the corresponding $\theta_k$'s of the AFM are determined
  
  $\Rightarrow \theta_k = \frac{\beta_k}{\alpha}$ or $\theta' = \frac{\beta'}{\alpha}$

- The acceleration factor $e^{\theta'Z}$ at the Weibull AFM indicates how a change in covariate values changes the time scale from the baseline time scale.
  
The factor $e^{\beta'Z}$ at the Weibull PHM indicates how much the baseline hazard rate of a lapse at any time changes when a policy has covariate vector $Z$.
  
  Note that $e^{\beta'Z}$ is the relative hazard rate of a lapse for a policy with covariate $Z$ compared to a policy with the baseline characteristics. This relative hazard rate is called the hazard ratio. This hazard ratio is constant over time (or the hazard rates are proportional).

- The PHM has the property of proportional hazard rates for fixed covariates. The hazard ratio (relative risk) of a lapse at time $t$ for a policy with risk factor $Z$, as compared to a policy with risk factor $Z^*$, is
  
  $$\frac{h(t \mid Z)}{h(t \mid Z^*)} = \frac{h_0(t) \exp\left\{\sum_{k=1}^{p} \beta_k Z_k\right\}}{h_0(t) \exp\left\{\sum_{k=1}^{p} \beta_k Z_k^*\right\}} = \exp\left\{\sum_{k=1}^{p} \beta_k (Z_k - Z_k^*)\right\}$$
  
  which is a constant. So the hazard rates are proportional (or the hazard ratio is constant).

- Estimates of the $\beta_k$'s can be used to provide estimates of hazard ratios. For a constant shape parameter in the Weibull distributions, the hazard ratios may be estimated from the exponent of the $\beta$-values in the Weibull regression model. These estimated hazard ratios are called risk scores.
4.4 **Comparison between the AFM and the POM**

- The log-logistic is the only continuous distribution which has the property of being both an AFM and a POM.
  The lifetimes under AFM $\sim \log\text{-logistic}(\lambda(e^{\vartheta'Z})^{\alpha}, \alpha)$.
  The lifetimes under POM $\sim \log\text{-logistic}(\lambda e^{{\mathbf{\beta}'}Z}, \alpha)$.

- There is a direct correspondence between the parameters of the log-logistic under these two models. It follows that when the $\beta_k$'s in the linear component of the POM are divided by $\alpha$, the corresponding $\theta_k$'s of the AFM are determined

  \[ \Rightarrow \theta_k = \frac{\beta_k}{\alpha} \text{ or } \theta' = \frac{\mathbf{\beta'}}{\alpha} \]

- The acceleration factor $e^{\vartheta'Z}$ at the log-logistic AFM indicates how a change in covariate values changes the time scale from the baseline time scale. The factor $e^{{\mathbf{\beta}'}Z}$ at the log-logistic POM indicates how much the baseline odds of a lapse at any time changes when a policy has covariate vector $Z$. Note that $e^{{\mathbf{\beta}'}Z}$ is the relative odds of a lapse for a policy with covariate $Z$ compared to a policy with the baseline characteristics. This relative odds is called the odds ratio. This odds ratio is constant over time (or the odds are proportional).

- The POM has the property of convergent hazard rates or the property of proportional odds for time-dependent covariates or non-proportional hazard rates for time-dependent covariates.

  The ratio of the hazard rate for the $j^{th}$ policy to the baseline hazard rate, namely $\frac{h_j(t)}{h_0(t)}$, converges from the value $\exp(-\sum_{k=1}^{p} \beta_k Z_k)$ at time $t=0$ to the value $1$ at time $t = \infty$.

- Estimates of the $\beta_k$'s can be used to provide estimates of odds ratios. For a constant shape parameter in the log-logistic distributions, the odds ratios may be estimated from the exponent of the $\beta$-values in the log-logistic regression model. These estimated odds ratios are called indices.
4.5 Log-linear Presentation of Models for Survival Data

4.5.1 A linear regression model for the log of the hazard ratio

In the AFM the hazard rate of a lapse for a policy with risk vector \( Z = (Z_1, Z_2, ..., Z_p)' \) and regression coefficients \( \theta = (\theta_1, \theta_2, ..., \theta_p)' \) is modelled as \( h(t|Z) = h_0(t)e^{\theta'Z} \) while in the PHM the hazard rate of a lapse for a policy with risk vector \( Z = (Z_1, Z_2, ..., Z_p)' \) and regression coefficients \( \beta = (\beta_1, \beta_2, ..., \beta_p)' \) is modelled as \( h(t|Z) = h_0(t)e^{\beta'Z} \).

The relative hazard rate for a policy with covariate \( Z \) compared to a policy with the baseline characteristics is termed the hazard ratio (relative risk or risk score)

\[
\Rightarrow \text{hazard ratio } \frac{h(t|Z)}{h_0(t)} = e^{\theta'Z} = e^{\beta'Z} \text{ is constant over time}
\]

\[
\Rightarrow \log(\text{hazard ratio}) \text{ is modelled as}
\]

\[
\ln \frac{h(t|Z)}{h_0(t)} = \theta'Z = \beta'Z = \sum_{k=1}^{p} \beta_k Z_k
\]

4.5.2 A linear regression model for the log of the odds ratio

In the AFM the odds of a lapse for a policy with risk vector \( Z = (Z_1, Z_2, ..., Z_p)' \) and regression coefficients \( \theta = (\theta_1, \theta_2, ..., \theta_p)' \) is modelled as \( \frac{1 - S(t|Z)}{S(t|Z)} = e^{\theta'Z} \cdot \frac{1 - S_0(t)}{S_0(t)} \) while in the POM the odds of a lapse for a policy with risk vector \( Z = (Z_1, Z_2, ..., Z_p)' \) and regression coefficients \( \beta = (\beta_1, \beta_2, ..., \beta_p)' \) is modelled as \( \frac{1 - S(t|Z)}{S(t|Z)} = e^{\beta'Z} \cdot \frac{1 - S_0(t)}{S_0(t)} \).

The relative odds of a lapse for a policy with covariate \( Z \) compared to a policy with the baseline characteristics is termed the odds ratio (relative odds or index)

\[
\Rightarrow \text{odds ratio } \frac{1 - S(t|Z)}{S(t|Z)} = \frac{1 - S_0(t)}{S_0(t)} = e^{\theta'Z} = e^{\beta'Z} \text{ is constant over time}
\]

\[
\Rightarrow \log(\text{odds ratio}) \text{ is modelled as}
\]
4.5.3 A linear regression model for log-time

Consider the following linear log-time regression model that describes the linear relationship between log-time and the covariate values.

\[ Y = \ln T = \mu + \gamma'Z + \sigma W \]

\( W \) is the error distribution, \( \mu \) is the intercept, \( \sigma \) is the scale parameter and \( \gamma' = (\gamma_1, \gamma_2, \ldots, \gamma_p) \) is a vector of regression coefficients that are interpreted similar to those in standard normal theory regression.

A variety of models is discussed by [4] that can be used for \( W \), or equivalently for \( T \) or \( S_0 \). Note that \( S_0(t) \) denotes the survivor function of \( T = e^Y \) when \( Z = 0 \), that is \( S_0(t) \) is the survivor function of \( e^{\mu + \sigma W} \). Then the linear log-time regression model is equivalent to the AFM with \( \theta = -\gamma \).

- If \( W \) has the standard extreme value distribution, that is \( W \sim EV(1, 0) \), with density
  \[ f(w) = \exp \{ (w - \exp(w)) \} \quad -\infty < w < \infty \]
  then \( T \) has an underlying Weibull\((\lambda, \alpha)\) distribution. This model leads to

  1. an AFM for \( T \) with a Weibull baseline survivor function with parameters
     \[ \lambda = \exp \left\{ -\mu \sigma \right\}, \alpha = \frac{1}{\sigma} \quad \text{and} \quad \theta_k = -\gamma_k \quad k = 1, 2, \ldots, p \]
  2. a PHM for \( T \) with a Weibull baseline hazard function with parameters
     \[ \lambda = \exp \left\{ -\mu \sigma \right\}, \alpha = \frac{1}{\sigma} \quad \text{and} \quad \beta_k = \theta_k \alpha = -\frac{\gamma_k}{\sigma} \quad k = 1, 2, \ldots, p \]

- If \( W \) has the standard logistic distribution with density
  \[ f(w) = \frac{\exp(w)}{(1 + \exp(w))^2} \quad -\infty < w < \infty \]
  then \( T \) has an underlying log-logistic\((\lambda, \alpha)\) distribution. This model leads to
1. an AFM for $T$ with a log-logistic baseline survivor function with parameters
\[ \lambda = \exp \left\{ -\frac{\mu}{\sigma} \right\}, \alpha = \frac{1}{\sigma} \quad \text{and} \quad \theta_k = -\gamma_k \quad k = 1, 2, ..., p \]

2. a POM for $T$ with a log-logistic baseline survivor function with parameters
\[ \lambda = \exp \left\{ -\frac{\mu}{\sigma} \right\}, \alpha = \frac{1}{\sigma} \quad \text{and} \quad \beta_k = \theta_k \alpha = -\frac{\gamma_k}{\sigma} \quad k = 1, 2, ..., p \]

## 4.6 Maximum Likelihood Estimation

### 4.6.1 Introduction

The standard way of fitting parametric regression models to an observed set of survival data with covariates is to use the method of maximum likelihood. Maximum likelihood estimation for the Weibull and log-logistic regression models has been discussed in [18, 22]. The construction of the likelihood functions for continuous and grouped survival data with covariates is now discussed.

### 4.6.2 Likelihood function for random right-censored continuous data

The right-censored survival data set consists of triplets $(T_j, \delta_j, Z_j)$ \quad $j = 1, 2, ..., n$ \quad where

- $T_j$ = lifetime for the $j^{th}$ policy
- $\delta_j$ = lapse indicator for the $j^{th}$ policy \quad $\delta_j = \begin{cases} 1 & \text{if policy has lapsed} \\ 0 & \text{if lifetime is right-censored} \end{cases}$
- $Z_j = (Z_{j1}, Z_{j2}, ..., Z_{jp})'$ is the vector of explanatory variables for the $j^{th}$ policy at a fixed time.

The likelihood function is constructed by considering the contribution to the likelihood of the triplets $(T_j, \delta_j = 1, Z_j)$ and $(T_j, \delta_j = 0, Z_j)$ separately \quad $j = 1, 2, ..., n$.

- For a specific triplet $(t, \delta_i = 1, Z)$ the observed survival time is $t$. Thus the contribution to the likelihood of this triplet is the probability that a policy with covariate vector $Z$ lapse at time $t$. This probability is given by the density function $f(t|Z)$.

- For a specific triplet $(t, \delta_i = 0, Z)$ the survival time is at least $t$. Thus the contribution to the likelihood of this triplet is the probability that a policy with covariate vector $Z$ survives at least time $t$. This probability is given by the survivor function $S(t|Z)$. 
The complete likelihood for the $i^{th}$ policy under random censoring is
\[
[f(t_j|Z_j)]^\delta_j \times [S(t_j|Z_j)]^{1-\delta_j} \quad j = 1, 2, \ldots, n
\] (4.6.1)

Under the assumption of $n$ independent censored and observed survival times, the full likelihood function is obtained by multiplying the respective contributions of the $n$ triplets. This gives the likelihood function
\[
L(\eta) = \prod_{i=1}^{n} [f(t_i|Z_i)]^{\delta_i} \times [S(t_i|Z_i)]^{1-\delta_i}
\] (4.6.2)

where $\eta$ is the vector of parameters of the survival model. The log-likelihood function
\[
\ln L(\eta) = \sum_{i=1}^{n} \{\delta_i \cdot \ln[f(t_i|Z_i)] + (1 - \delta_i) \cdot \ln[S(t_i|Z_i)]\}
\] (4.6.3)

is maximized to obtain the maximum likelihood estimators of the unknown parameters $\eta$. The procedure to obtain the values of the MLE involves taking derivatives of $\ln L(\eta)$ with respect to $\eta$, setting these equations equal to zero, and solving for $\eta$.

### 4.6.3 Likelihood function for right-censored grouped data

Consider the grouped data case, as in [24], where the $n$ lifetimes of policies are grouped into $k$ adjacent, non-overlapping fixed intervals
\[
I_j = [a_{j-1}; a_j) \quad j = 1, 2, \ldots, k
\]

with $a_0 = 0$ and $a_k = \infty$.

For complete data, the $n$ observed lifetimes are grouped into $k$ intervals so that $n = d_1 + d_2 + \ldots + d_k$ with $d_j$=number of lapses in $I_j$.

The unconditional probability of a lapse in $I_j$ is
\[
\pi_j(\eta) = S(a_{j-1}, \eta) - S(a_j, \eta) \quad j = 1, 2, \ldots, k.
\]

Then $(d_1, d_2, \ldots, d_k)$ has a multinomial probability function
\[
\frac{n!}{d_1!d_2!\ldots d_k!} \pi_1(\eta)^{d_1} \pi_2(\eta)^{d_2} \ldots \pi_k(\eta)^{d_k}.
\]

The likelihood function can thus be taken as
\[
L(\eta) = n! \prod_{j=1}^{k} \left\{ \frac{[S(a_{j-1}, \eta) - S(a_j, \eta)]^{d_j}}{d_j!} \right\}
\] (4.6.4)
For **incomplete data**, where the \( n \) censored and observed lifetimes are grouped into \( k \) intervals, it is further assumed that the \( W_j \) censored lifetimes in \( I_j \) occur at the midpoint of the interval \( a_j^* = a_{j-1} + \frac{1}{2}h_j \) with \( h_j = a_j - a_{j-1} \) the length of interval \( I_j \).

For interval \( I_j = [a_{j-1}; a_j) \), **conditional** on surviving till \( a_{j-1} \),

- the probability of a lapse is
  \[
  q_j(\eta) = \frac{S(a_{j-1}, \eta) - S(a_j, \eta)}{S(a_{j-1}, \eta)}
  \]
- the probability of surviving until \( a_j^* \) is
  \[
  p_j^*(\eta) = \frac{S(a_{j-1}, \eta) - S(a_j^*, \eta)}{S(a_{j-1}, \eta)}
  \]
- the probability of surviving the full interval \( I_j \) is
  \[
  p_j(\eta) = 1 - q_j(\eta) = 1 - \frac{S(a_{j-1}, \eta) - S(a_j, \eta)}{S(a_{j-1}, \eta)} = \frac{S(a_j, \eta)}{S(a_{j-1}, \eta)}
  \]

The **conditional** likelihood for interval \( I_j \) is
\[
L_j(\eta) \propto [q_j(\eta)]^{d_j} \cdot [p_j^*(\eta)]^{W_j} \cdot [p_j(\eta)]^{Y_j-d_j-W_j} \tag{4.6.5}
\]
where \( Y_j \) is the number of policies at risk of lapsing in \( I_j \), that is still alive at \( a_{j-1} \).

The overall likelihood function is
\[
L(\eta) = \prod_{j=1}^{k} L_j(\eta) \tag{4.5.6}
\]

If class intervals are narrow, another possibility is to treat the data as continuous and assume that all lifetimes in interval \( I_j \) occur at the interval midpoint.

**4.6.4 Likelihood function for the linear model in log-time**

A log-linear regression model (a linear regression model in log-time) is discussed by [22] and could be fitted to a survival data set of the form
\[
Y = \ln T = \mu + \gamma'Z + \sigma W
\]
where $W$ is the error distribution, $\mu$ is the intercept, $\sigma$ is the scale parameter and $\gamma' = (\gamma_1, \gamma_2, ..., \gamma_p)$ is a vector of regression coefficients.

Consider the $n$ triplets $(y_j, \delta_j, Z_j)$ $j = 1, 2, ..., n$ in the data set with $y_j = \ln(t_j)$.

The basic form of the likelihood function for random right-censored continuous data is, from Equation 4.6.2, equal to

$$L(\mu, \gamma, \sigma) = \prod_{i=1}^{n} [f_Y(y_i)]^{\delta_i} \cdot [S_Y(y_i)]^{1-\delta_i}$$

$$= \prod_{i=1}^{n} \left[ f_W\left(\frac{y_i - \mu - \gamma'Z_i}{\sigma}\right) \cdot \frac{1}{\sigma} \right]^{\delta_i} \cdot \left[ S_W\left(\frac{y_i - \mu - \gamma'Z_i}{\sigma}\right) \right]^{1-\delta_i}$$

(4.6.7)

The log-likelihood function for random right-censored continuous data is

$$\ln L(\mu, \gamma, \sigma) = \sum \delta_i \cdot \ln \left[ f_W\left(\frac{y_i - \mu - \gamma'Z_i}{\sigma}\right) \cdot \frac{1}{\sigma} \right] + \sum (1 - \delta_i) \cdot \ln \left[ S_W\left(\frac{y_i - \mu - \gamma'Z_i}{\sigma}\right) \right]$$

(4.6.8)

with

the first sum over observed lifetimes (uncensored observations)
the second sum over right-censored observations.

The basic form of the likelihood function for interval-censored data is

$$L(\mu, \gamma, \sigma) = \prod_{i=1}^{n} [f_Y(y_i)]^{\delta_i} \cdot [S_Y(y_i)]^{1-\delta_i} \cdot [1 - S_Y(y_i)]^{\delta_i} \cdot [S_Y(b_i) - S_Y(y_i)]^{1-\delta_i}$$

$$= \prod_{i=1}^{n} \left[ f_W\left(\frac{y_i - \mu - \gamma'Z_i}{\sigma}\right) \cdot \frac{1}{\sigma} \right]^{\delta_i} \cdot \left[ S_W\left(\frac{y_i - \mu - \gamma'Z_i}{\sigma}\right) \right]^{1-\delta_i} \cdot$$

$$\left[ 1 - S_W\left(\frac{y_i - \mu - \gamma'Z_i}{\sigma}\right) \right]^{\delta_i} \cdot \left[ S_W\left(\frac{b_i - \mu}{\sigma}\right) - S_W\left(\frac{y_i - \mu - \gamma'Z_i}{\sigma}\right) \right]^{1-\delta_i}$$

(4.6.9)

with $b_i$ the lower end of a censoring interval.

The log-likelihood function for interval-censored data is

$$\ln L(\mu, \gamma, \sigma) = \sum \delta_i \cdot \ln \left[ f_W\left(\frac{y_i - \mu - \gamma'Z_i}{\sigma}\right) \cdot \frac{1}{\sigma} \right] + \sum (1 - \delta_i) \cdot \ln \left[ S_W\left(\frac{y_i - \mu - \gamma'Z_i}{\sigma}\right) \right]$$

$$+ \sum (\delta_i) \cdot \ln \left[ 1 - S_W\left(\frac{y_i - \mu - \gamma'Z_i}{\sigma}\right) \right]$$

$$+ \sum (1 - \delta_i) \cdot \ln \left[ S_W\left(\frac{b_i - \mu}{\sigma}\right) - S_W\left(\frac{y_i - \mu - \gamma'Z_i}{\sigma}\right) \right]$$
with
the first sum over observed lifetimes (uncensored observations)
the second sum over right-censored observations
the third sum over left-censored observations
the fourth sum over interval-censored observations.

4.6.5 Maximum likelihood estimators

Maximum likelihood estimates for the Weibull and log-logistic regression models must be found. Most computer software packages for survival analysis, including SAS, use the linear log-time regression model version. Refer to [4]. Maximum likelihood estimators of the log-linear parameters $\mu$, $\sigma$ and $\gamma' = (\gamma_1, \gamma_2, \ldots, \gamma_p)$ are found numerically, and routines to do so are available in the SAS statistical package. SAS allows for right-, left- and interval-censored data. The SAS program appear in Appendix A.

The invariance property of the SAS maximum likelihood estimators of $\mu, \sigma$ and $\gamma_k \quad k = 1, 2, \ldots, p$ in the log-linear model provides estimates of parameters of the three models (AFM, PHM or POM). Then the parameters of the three models are functions of these estimates and can be computed in the following way:

- If $W$ has the standard extreme value distribution then $T$ has an underlying Weibull($\lambda, \alpha$) distribution. The linear model for log-time then leads to
  
  1. an AFM for $T$ with a Weibull baseline survivor function with estimated parameters

\[
\hat{\lambda} = \exp \left\{ -\hat{\mu} \right\}, \hat{\alpha} = \frac{1}{\hat{\sigma}} \quad \text{and} \quad \hat{\theta}_k = -\hat{\gamma}_k \quad k = 1, 2, \ldots, p
\]  

(4.6.11)

  2. a PHM for $T$ with a Weibull baseline hazard function with parameters

\[
\hat{\lambda} = \exp \left\{ \frac{-\hat{\mu}}{\hat{\sigma}} \right\}, \hat{\alpha} = \frac{1}{\hat{\sigma}} \quad \text{and} \quad \hat{\beta}_k = \hat{\theta}_k \hat{\alpha} = \frac{-\hat{\gamma}_k}{\hat{\sigma}} \quad k = 1, 2, \ldots, p
\]  

(4.6.12)

- If $W$ has the standard logistic distribution then $T$ has an underlying log-logistic($\lambda, \alpha$) distribution. The linear model for log-time then leads to
  
  1. an AFM for $T$ with a log-logistic baseline survivor function with parameters

\[
\hat{\lambda} = \exp \left\{ -\hat{\mu} \right\}, \hat{\alpha} = \frac{1}{\hat{\sigma}} \quad \text{and} \quad \hat{\theta}_k = -\hat{\gamma}_k \quad k = 1, 2, \ldots, p
\]  

(4.6.13)
2. a POM for $T$ with a log-logistic baseline survivor function with parameters

$$
\hat{\lambda} = \exp \left\{ \frac{-\hat{\mu}}{\hat{\sigma}} \right\}, \quad \hat{\alpha} = \frac{1}{\hat{\sigma}} \quad \text{and} \quad \hat{\beta}_k = \hat{\theta}_k \hat{\alpha} = \frac{-\hat{\gamma}_k}{\hat{\sigma}} \quad k = 1, 2, \ldots, r \quad (4.6.14)
$$

The variance-covariance matrix of the log-linear parameters $\mu$, $\gamma$ and $\sigma$, obtained from the observed information matrix, are also available in this package.

Using the delta method, the approximate variance-covariance matrix for these estimates, based on the estimates and their covariances in the log-linear model, is

$$
cov(\hat{\beta}_j, \hat{\beta}_k) = \frac{cov(\hat{\gamma}_j, \hat{\gamma}_k)}{\hat{\sigma}^2} - \hat{\gamma}_j \frac{cov(\hat{\gamma}_j, \hat{\sigma})}{\hat{\sigma}^3} - \hat{\gamma}_k \frac{cov(\hat{\gamma}_k, \hat{\sigma})}{\hat{\sigma}^3} + \hat{\gamma}_j \hat{\gamma}_k \frac{var(\hat{\sigma})}{\hat{\sigma}^4} \quad (4.6.15)
$$

$$
var(\hat{\lambda}) = \exp \left( \frac{-2\hat{\mu}}{\hat{\sigma}} \right) \cdot \left[ var(\hat{\mu}) + \hat{\mu}^2 \frac{var(\hat{\sigma})}{\hat{\sigma}^4} - 2\hat{\mu} \frac{cov(\hat{\mu}, \hat{\sigma})}{\hat{\sigma}^3} \right] \quad (4.6.16)
$$

$$
var(\hat{\alpha}) = \frac{var(\hat{\sigma})}{\hat{\sigma}^4} \quad (4.6.17)
$$

$$
cov(\hat{\beta}_j, \hat{\lambda}) = \exp \left( \frac{-\hat{\mu}}{\hat{\sigma}} \right) \cdot \left[ \frac{cov(\hat{\gamma}_j, \hat{\mu})}{\hat{\sigma}^2} - \hat{\gamma}_j \frac{cov(\hat{\gamma}_j, \hat{\sigma})}{\hat{\sigma}^3} - \hat{\mu} \frac{cov(\hat{\mu}, \hat{\sigma})}{\hat{\sigma}^3} + \hat{\gamma}_j \hat{\mu} \frac{var(\hat{\sigma})}{\hat{\sigma}^4} \right] \quad (4.6.18)
$$

$$
cov(\hat{\beta}_j, \hat{\alpha}) = \frac{cov(\hat{\gamma}_j, \hat{\sigma})}{\hat{\sigma}^3} - \hat{\gamma}_j \frac{var(\hat{\sigma})}{\hat{\sigma}^4} \quad (4.6.19)
$$

$$
cov(\hat{\lambda}, \hat{\alpha}) = \exp \left( \frac{-\hat{\mu}}{\hat{\sigma}} \right) \cdot \left[ \frac{cov(\hat{\mu}, \hat{\sigma})}{\hat{\sigma}^3} - \hat{\mu} \frac{var(\hat{\sigma})}{\hat{\sigma}^4} \right] \quad (4.6.20)
$$

Once maximum likelihood estimates of the parameters $\lambda$ and $\alpha$ are computed, estimates of the survivor function and the hazard function are available for the distribution of $T$ (or $Y = \ln(T)$), that is the Weibull (or extreme value) and log-logistic (or logistic).

In the above regression models, the effect of the covariates is to alter the scale parameter, while the shape parameter remains constant. The article [28] discusses how to extend the semi-parametric Cox's PHM to alter both the scale and the shape parameters. The standard parametric regression model fitting that is performed by PROC LIFEREG of SAS can not alter both parameters, but the method of maximum likelihood estimation subject to constraints in the next section can do it.

Graphical checks to determine whether or not a certain parametric model is reasonable, is given by [4]. These tests are based on the linear relationship between some function of the survivor function and some function of time.
4.7 Maximum Likelihood Estimation subject to Constraints

4.7.1 Introduction

The parametric regression model must describe the basic underlying distribution of survival time, but it must also characterize how that distribution changes as a function of the covariates. The effect of the covariates is

- to alter the scale parameter, while the shape parameter remains constant.
- to alter both the scale and the shape parameters.

In the case of grouped survival data, a survival distribution is fitted for each level of a risk factor or combination of levels of risk factors by using maximum likelihood estimation subject to constraints for estimating the parameters of the regression model. A detailed description of the development of this theory is given for one categorical risk factor on three levels, where the effect of the risk factor is either to keep the shape parameter \( \alpha \) constant or to alter it. Then it is shown how to deal with a continuous risk factor when fitting the regression model when the shape parameter remains constant. In the last part of this chapter, the theory is extended to a regression model with two categorical risk factors.

The fitting of a log-logistic regression model and a Weibull regression model will be discussed for staggered entry of policies. These two distributions are used, because the log-logistic is the only continuous distribution which has the property of being both an AFM and a POM and the Weibull is the only continuous distribution which has the property of being both an AFM and a PHM.

4.7.2 Notation for a regression model with one risk factor at staggered entry

Consider a categorical risk factor \( A \) on three levels \( A_1, A_2 \) and \( A_3 \).

The notation for staggered entry of policies with four different entry periods, as described in chapter three, can be extended in the following way when fitting a regression model with one risk factor. For simplicity, assume that \( k \), the number of class intervals for the first entry, is equal to seven.

The combined relative frequency vector \( p' \) is defined as

\( p_{il} \) is the relative frequency vector for the \( i^{th} \) entry group and the \( l^{th} \) level of risk factor \( A \), corresponding to \( n_{il}p_{il} \) being multinomial \( (n_{il}; \pi_{il}) \) distributed

\[ i = 1, 2, 3, 4 \quad \text{and} \quad l = 1, 2, 3. \]

\( p_{1l} = (p_{11,1}, p_{11,2}, p_{11,3}, p_{11,4}, p_{11,5}, p_{11,6}, p_{11,7})' \) is a \( 7 \times 1 \) relative frequency vector

\( p_{2l} = (p_{21,1}, p_{21,2}, p_{21,3}, p_{21,4}, p_{21,5}, p_{21,6})' \) is a \( 6 \times 1 \) relative frequency vector

\( p_{3l} = (p_{31,1}, p_{31,2}, p_{31,3}, p_{31,4}, p_{31,5})' \) is a \( 5 \times 1 \) relative frequency vector

\( p_{4l} = (p_{41,1}, p_{41,2}, p_{41,3}, p_{41,4})' \) is a \( 4 \times 1 \) relative frequency vector

\[ \text{and} \]

\( \pi_{1l} = (\pi_{11,1}, \pi_{11,2}, \pi_{11,3}, \pi_{11,4}, \pi_{11,5}, \pi_{11,6}, \pi_{11,7})' \) is a \( 7 \times 1 \) probability vector

\( \pi_{2l} = (\pi_{21,1}, \pi_{21,2}, \pi_{21,3}, \pi_{21,4}, \pi_{21,5}, \pi_{21,6})' \) is a \( 6 \times 1 \) probability vector

\( \pi_{3l} = (\pi_{31,1}, \pi_{31,2}, \pi_{31,3}, \pi_{31,4}, \pi_{31,5})' \) is a \( 5 \times 1 \) probability vector

\( \pi_{4l} = (\pi_{41,1}, \pi_{41,2}, \pi_{41,3}, \pi_{41,4})' \) is a \( 4 \times 1 \) probability vector \( \quad l = 1, 2, 3. \)

The vectors \( x_i \quad i = 1, 2, 3, 4 \) of upper class boundaries for the \( i^{th} \) entry group are

\[
\begin{align*}
    x_1 &= \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \\ x_5 \\ x_6 \end{pmatrix} \\
    x_2 &= \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \\ x_5 \\ x_6 \end{pmatrix} \\
    x_3 &= \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \\ x_5 \\ x_6 \end{pmatrix} \\
    x_4 &= \begin{pmatrix} x_1 \\ x_2 \\ x_3 \end{pmatrix} 
\end{align*}
\]

The number of entries per cell in the cross tabulation of entry period and risk factor \( A \) can be summarized in table 4.1.
Table 4.1: **Number of entries per cell in cross table of entry period and risk factor A**

Define matrix $S$ as

$$S = \begin{pmatrix} S_{A_1} \\ S_{A_2} \\ S_{A_3} \end{pmatrix}$$

where $S_{A_l} = \text{block}(S_1, S_2, S_3, S_4)$ for $l = 1, 2, 3$ with

$$S_1 = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & 0 & 0 \\ 1 & 1 & 1 & 0 & 0 & 0 \\ 1 & 1 & 1 & 1 & 0 & 0 \\ 1 & 1 & 1 & 1 & 1 & 0 \end{pmatrix}$$

$$S_2 = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & 0 & 0 \\ 1 & 1 & 1 & 0 & 0 & 0 \\ 1 & 1 & 1 & 1 & 0 & 0 \\ 1 & 1 & 1 & 1 & 1 & 0 \end{pmatrix}$$

$$S_3 = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 1 & 1 & 1 & 0 \\ 1 & 1 & 1 & 1 \end{pmatrix}$$

$$S_4 = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 1 & 1 & 1 & 0 \end{pmatrix}.$$
is a $54 \times 66$ matrix. $S_{A_l}$ is a $18 \times 22$ matrix $l=1,2,3$ and has the following form:

$$S_{A_l} = \begin{pmatrix}
1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
1 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
1 & 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 1 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 1 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 1 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 1 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1
\end{pmatrix}$$

The variance-covariance matrix $\mathbf{V}$ to be used is the estimated variance-covariance matrix of the multinomial distribution for each combination of entry period and risk factor level

$$\mathbf{V} = \text{block}(\tilde{\mathbf{V}}_{A_1}, \tilde{\mathbf{V}}_{A_2}, \tilde{\mathbf{V}}_{A_3})$$

where

$$\tilde{\mathbf{V}}_{A_l} = \text{block}(\tilde{\mathbf{V}}_{A_{1,l}}, \tilde{\mathbf{V}}_{A_{2,l}}, \tilde{\mathbf{V}}_{A_{3,l}}, \tilde{\mathbf{V}}_{A_{4,l}}) \quad l = 1,2,3$$

and

$$\tilde{\mathbf{V}}_{A_{i,l}} = \frac{1}{n_{il}} [\text{diag}(p_{il}) - p_{il}p_{il}'] \quad i = 1,2,3,4 \quad \text{and} \quad l = 1,2,3$$

Note that $\tilde{\mathbf{V}}_{A_{1,l}}$ is a $7 \times 7$, $\tilde{\mathbf{V}}_{A_{2,l}}$ is a $6 \times 6$, $\tilde{\mathbf{V}}_{A_{3,l}}$ is a $5 \times 5$ and $\tilde{\mathbf{V}}_{A_{4,l}}$ is a $4 \times 4$ matrix so that $\tilde{\mathbf{V}}_{A_l}$ is a $22 \times 22$ matrix $l = 1,2,3$ and $\mathbf{V}$ is a $66 \times 66$ matrix.

### 4.7.3 The log-logistic regression model: staggered entry, shape parameter remains constant

In this model the effect of the risk factor is to alter the scale parameter $\lambda$, while the shape parameter $\alpha$ remains constant.

Equation 3.3 .23 can be extended to take covariates into account as follows:

$$\ln \left( \frac{1 - S(x)}{S(x)} \right) = \ln \lambda \cdot 1 + \beta' \mathbf{Z} + \alpha \cdot \ln x$$ (4.7.1)

Consider a risk factor $A$ on three levels $A_1$, $A_2$ and $A_3$. Two dummy variables $Z_{A_1}$ and $Z_{A_2}$ are defined for levels $A_1$ and $A_2$ in such a way that the regression coefficient $\beta_{A_3}$ of level $A_3$ is equal to $-(\beta_{A_1} + \beta_{A_2})$, that means $\left\{ \sum_{k=1}^{3} \beta_{A_k} \right\} = 0$. 

Then Equation 4.7.1 becomes

\[
\ln \left( \frac{1 - S(x)}{S(x)} \right) = \ln \lambda \cdot 1 + (\beta_{A_1} Z_{A_1} + \beta_{A_2} Z_{A_2}) + \alpha \cdot \ln x \quad (4.7.2)
\]

or

\[
\ln \left( \frac{1 - S(x)}{S(x)} \right) = \ln \left( \frac{F(x)}{1 - F(x)} \right) = \ln \left( \frac{\pi_S}{1 - \pi_S} \right) = \ln (\pi_S) - \ln (1 - \pi_S)
\]

\[
\begin{pmatrix}
1 & 1 & 0 & \ln x_1 \\
1 & 1 & 0 & \ln x_2 \\
1 & 1 & 0 & \ln x_3 \\
1 & 1 & 0 & \ln x_4 \\
1 & 0 & 1 & \ln x_1 \\
1 & 0 & 1 & \ln x_2 \\
1 & 0 & 1 & \ln x_3 \\
1 & 0 & 1 & \ln x_4 \\
\end{pmatrix}
\begin{pmatrix}
\ln \lambda \\
\beta_{A_1} \\
\beta_{A_2} \\
\alpha \\
\end{pmatrix}
\]

\[
= \ln \lambda \cdot
\begin{pmatrix}
1 \\
1 \\
1 \\
1 \\
0 \\
0 \\
0 \\
0 \\
\end{pmatrix} + \beta_{A_1} \cdot
\begin{pmatrix}
0 \\
0 \\
0 \\
0 \\
1 \\
1 \\
1 \\
1 \\
\end{pmatrix} + \beta_{A_2} \cdot
\begin{pmatrix}
-1 \\
-1 \\
-1 \\
-1 \\
-1 \\
-1 \\
-1 \\
-1 \\
\end{pmatrix} + \alpha \cdot
\begin{pmatrix}
0 \\
0 \\
0 \\
0 \\
1 \\
1 \\
1 \\
1 \\
\end{pmatrix}
\]

\[
= \begin{pmatrix}
\ln x_1 \\
\ln x_2 \\
\ln x_3 \\
\ln x_4 \\
\ln x_1 \\
\ln x_2 \\
\ln x_3 \\
\ln x_4 \\
\end{pmatrix}
\]
\[ \Rightarrow \ln \left( \frac{\pi_S}{1 - \pi_S} \right) = X_1 \begin{pmatrix} \ln \lambda \\ \beta_{A_1} \\ \beta_{A_2} \\ \alpha \end{pmatrix} \]  

(4.7.3)

Equation 4.7.3 is a linear model in the parameters $\ln \lambda$, $\beta_{A_1}$, $\beta_{A_2}$ and $\alpha$. This model is equivalent to

\[
\left( I - X_1(X_1'X_1)^{-1}X_1' \right) \cdot \ln \left( \frac{\pi_S}{1 - \pi_S} \right) = 0 \\
C \cdot \ln \left( \frac{\pi_S}{1 - \pi_S} \right) = 0 \\
g(\pi) = 0
\]

$C$ is the projection matrix orthogonal to the columns of the design matrix $X_1$. Note that $CX_1 = 0$.

The function $g(\pi) = 0$ satisfies the conditions of Proposition 1 and the estimation algorithm can be used to estimate the $\lambda$'s and $\alpha$'s of the log-logistic distributions for the three levels of the risk factor $A$.

To summarize, the constraints imposed by the log-logistic distribution are specified by

\[
g(\pi) = C \cdot \ln \left\{ \frac{\pi_S}{1 - \pi_S} \right\} = C \cdot \ln \left[ \frac{S \cdot \pi}{1 - S \cdot \pi} \right] = C \cdot \left[ \ln(S \cdot \pi) - \ln(1 - S \cdot \pi) \right] = 0
\]

(4.7.4)

with

\[
C = I - X_1(X_1'X_1)^{-1}X_1'
\]

(4.7.5)

The derivative of $g(\pi)$ with respect to $\pi$ is

\[
G_{\pi} = \frac{\partial g(\pi)}{\partial \pi} = C \cdot \left[ \text{diag} \left( \frac{1}{\pi_S} \right) + \text{diag} \left( \frac{1}{1 - \pi_S} \right) \right] \cdot S
\]

(4.7.6)

\[
= C \cdot [D_3^{-1} + D_2^{-1}] \cdot S
\]

(4.7.7)

where $D_3$ and $D_2$ are diagonal matrices with the elements of $\pi_S$ and $1 - \pi_S$, respectively, on the main diagonal.
The estimated vector of probabilities in this case is

\[
\hat{\pi}_c = p - (G_p V)' (G_p V G_p)'^{-1} \cdot C \cdot \ln \left\{ \frac{S \cdot p}{1 - S \cdot p} \right\}
\]  

(4.7.8)

with \(S\) and \(\hat{V}\), the estimated variance-covariance matrix, defined in section 4.7.2.

Since Equation 4.7.8 is still a function of the unknown parameter \(\pi\), the double iterative procedure must be implemented. Once the iterative procedure in Equation 4.7.8 has converged, the estimated parameters of the three log-logistic distributions can be solved from

\[
\begin{pmatrix}
\ln \hat{\lambda} \\
\hat{\beta}_{A1} \\
\hat{\beta}_{A2} \\
\hat{\alpha}
\end{pmatrix} = (X_1'X_1)^{-1}X_1' \cdot \ln \left\{ \frac{S \cdot \hat{\pi}_c}{1 - S \cdot \hat{\pi}_c} \right\}
\]  

(4.7.9)

and \(\hat{\beta}_{A3} = - (\hat{\beta}_{A1} + \hat{\beta}_{A2})\).

The estimated lambda parameters of the three log-logistic distributions for the three risk factor levels then are

\[
\hat{\lambda}_{A1} = \exp(\ln \lambda + \hat{\beta}_{A1}) \\
\hat{\lambda}_{A2} = \exp(\ln \lambda + \hat{\beta}_{A2}) \\
\hat{\lambda}_{A3} = \exp(\ln \lambda + \hat{\beta}_{A3}).
\]

Consider Equation 4.7.2 where \(\ln(\text{odds})\) is modelled in terms of dummy variables \(Z_{A1}\) and \(Z_{A2}\)

\[
\Rightarrow \ln(\text{odds}) = \ln \lambda \cdot 1 + (\beta_{A1}Z_{A1} + \beta_{A2}Z_{A2}) + \alpha \cdot \ln x
\]

Take the summation over the risk factor levels, that gives

\[
\sum \{\ln(\text{odds})\} = \sum \{\ln \lambda \cdot 1\} + \sum \{(\beta_{A1} \cdot Z_{A1} + \beta_{A2} \cdot Z_{A2})\} + \sum \{\alpha \cdot \ln x\},
\]

but

\[
\sum \{(\beta_{A1} \cdot Z_{A1} + \beta_{A2} \cdot Z_{A2})\} = (\beta_{A1} \cdot 1 + \beta_{A2} \cdot 0) + (\beta_{A1} \cdot 0 + \beta_{A2} \cdot 1) + (\beta_{A1} \cdot (-1) + \beta_{A2} \cdot (-1))
\]

\[
= \beta_{A1} + \beta_{A2} + \beta_{A3}
\]

\[
= 0,
\]

therefore

\[
\sum \{\ln(\text{odds})\} = \sum \{\ln \lambda \cdot 1\} + \sum \{\alpha \cdot \ln x\}.
\]

\[
\Rightarrow \text{average}\{\ln(\text{odds})\} = \ln \lambda \cdot 1 + \alpha \cdot \ln x.
\]

The baseline log-logistic model in this context is defined as the log-logistic model at this average value of \(\ln(\text{odds})\).

The estimated lambda parameter of the baseline log-logistic distribution then is

\[
\hat{\lambda}_0 = \exp(\ln \lambda)
\]
so that

\[ \hat{\lambda}_{A_1} = \hat{\lambda}_0 \times \exp(\hat{\beta}_{A_1}) \]
\[ \hat{\lambda}_{A_2} = \hat{\lambda}_0 \times \exp(\hat{\beta}_{A_2}) \]
\[ \hat{\lambda}_{A_3} = \hat{\lambda}_0 \times \exp(\hat{\beta}_{A_3}) \].

These four log-logistic distributions all have the same estimated alpha parameter \( \hat{\alpha} \).

The SAS/IML program to fit a log-logistic regression model (constant shape parameter) to grouped survival data with staggered entry of policies appears in Appendix A.

4.7.4 **The log-logistic regression model: staggered entry, shape parameter alters**

In this model the effect of the risk factor is to alter both the scale parameter \( \lambda \) and the shape parameter \( \alpha \).

Then Equation 4.7 .1 becomes

\[
\ln \left( \frac{1 - S(x)}{S(x)} \right) = \ln \left( \frac{F(x)}{1 - F(x)} \right) = \ln \left( \frac{\pi_S}{1 - \pi_S} \right) = \ln(\pi_S) - \ln(1 - \pi_S)
\]

\[
\begin{pmatrix}
1 \\
1 \\
1 \\
1 \\
1
\end{pmatrix}
+ \begin{pmatrix}
\beta_{A_1} \\
\beta_{A_2} \\
\alpha_{A_1} \\
\alpha_{A_2} \\
\end{pmatrix}
+ \begin{pmatrix}
\ln x_1 \\
\ln x_2 \\
\ln x_3 \\
\ln x_4 \\
\end{pmatrix}
= \ln \lambda
\]

\[
\begin{pmatrix}
1 \\
1 \\
1 \\
1 \\
1
\end{pmatrix}
+ \begin{pmatrix}
\ln x_1 \\
\ln x_2 \\
\ln x_3 \\
\ln x_4 \\
\end{pmatrix}
+ \begin{pmatrix}
0 \\
0 \\
0 \\
0 \\
\end{pmatrix}
= \ln \lambda
\]
\[
\begin{pmatrix}
1 & 1 & 0 & \ln x_1 & 0 & 0 \\
1 & 1 & 0 & \ln x_2 & 0 & 0 \\
1 & 1 & 0 & \ln x_3 & 0 & 0 \\
1 & 1 & 0 & \ln x_4 & 0 & 0 \\
1 & 0 & 1 & 0 & \ln x_1 & 0 \\
1 & 0 & 1 & 0 & \ln x_2 & 0 \\
1 & 0 & 1 & 0 & \ln x_3 & 0 \\
1 & 0 & 1 & 0 & \ln x_4 & 0 \\
1 & -1 & -1 & 0 & 0 & \ln x_1 \\
1 & -1 & -1 & 0 & 0 & \ln x_2 \\
1 & -1 & -1 & 0 & 0 & \ln x_3 \\
1 & -1 & -1 & 0 & 0 & \ln x_4 \\
\end{pmatrix}
\begin{pmatrix}
\ln \lambda \\
\beta_{A_1} \\
\beta_{A_2} \\
\alpha_{A_1} \\
\alpha_{A_2} \\
\alpha_{A_3} \\
\end{pmatrix}

\Rightarrow \ln \left( \frac{\pi_S}{1 - \pi_S} \right) = X_1 \begin{pmatrix}
\ln \lambda \\
\beta_{A_1} \\
\beta_{A_2} \\
\alpha_{A_1} \\
\alpha_{A_2} \\
\alpha_{A_3} \\
\end{pmatrix}

This is a linear model in the parameters $\ln \lambda$, $\beta_{A_1}$, $\beta_{A_2}$, $\alpha_{A_1}$, $\alpha_{A_2}$ and $\alpha_{A_3}$. This model is equivalent to

\[
\left( I - X_1(X_1'X_1)^{-1}X_1' \right) \ln \left( \frac{\pi_S}{1 - \pi_S} \right) = 0
\]

\[
C \cdot \ln \left( \frac{\pi_S}{1 - \pi_S} \right) = 0
\]

\[
g(\pi) = 0
\]

$C$ is the projection matrix orthogonal to the columns of the design matrix $X_1$. Note that $CX_1 = 0$.

The function $g(\pi) = 0$ satisfies the conditions of Proposition 1 and the estimation algorithm can be used to estimate the $\lambda$'s and $\alpha$'s of the log-logistic distributions for the three levels of the risk factor $A$.

To summarize, the constraints imposed by the log-logistic distribution are specified by
\[ g(\pi) = C \ln \left\{ \frac{\pi_S}{1 - \pi_S} \right\} = C \ln \left[ \frac{S \cdot \pi}{1 - S \cdot \pi} \right] = C \left[ \ln(S \cdot \pi) - \ln(1 - S \cdot \pi) \right] = 0 \]  
\text{(4.7.10)}

with
\[ C = I - X_1(X_1'X_1)^{-1}X_1'. \]  
\text{(4.7.11)}

The derivative of \( g(\pi) \) with respect to \( \pi \) is
\[ G_\pi = \frac{\partial g(\pi)}{\partial \pi} \]
\[ = C \cdot \left[ \text{diag} \left( \frac{1}{\pi_S} \right) + \text{diag} \left( \frac{1}{1 - \pi_S} \right) \right] \cdot S \]  
\text{(4.7.12)}
\[ = C \cdot \left[ D_3^{-1} + D_2^{-1} \right] \cdot S \]  
\text{(4.7.13)}

where
\( D_3 \) and \( D_2 \) are diagonal matrices with the elements of \( \pi_S \) and \( 1 - \pi_S \), respectively, on the main diagonal. \( S \) is a matrix composed from three matrices associated with the three levels of risk factor \( A \).

The estimated vector of probabilities in this case is
\[ \hat{\pi}_c = p - (G_\pi V)' (G_p V G_\pi')^{-1} \cdot C \ln \left\{ \frac{S \cdot p}{1 - S \cdot p} \right\} \]  
\text{(4.7.14)}

with \( S \) and \( \hat{V} \), the estimated variance-covariance matrix, defined in section 4.7.2.

Since Equation 4.7.14 is still a function of the unknown parameter \( \pi \), the double iterative procedure must be implemented. Once the iterative procedure in Equation 4.7.14 has converged, the estimated parameters of the three log-logistic distributions can be solved from
\[ \begin{pmatrix} \hat{\ln \lambda} \\ \hat{\beta}_{A_1} \\ \hat{\beta}_{A_2} \\ \hat{\alpha}_{A_1} \\ \hat{\alpha}_{A_2} \end{pmatrix} = (X_1'X_1)^{-1}X_1' \cdot \ln \left\{ \frac{S \cdot \hat{\pi}_c}{1 - S \cdot \hat{\pi}_c} \right\} \]  
\text{(4.7.15)}

and \( \hat{\beta}_{A_3} = -\left( \hat{\beta}_{A_1} + \hat{\beta}_{A_2} \right) \).

The estimated lambda parameters of the three log-logistic distributions for the three risk
factor levels then are
\[
\hat{\lambda}_{A_1} = \exp(\ln \hat{\lambda} + \hat{\beta}_{A_1}) \\
\hat{\lambda}_{A_2} = \exp(\ln \hat{\lambda} + \hat{\beta}_{A_2}) \\
\hat{\lambda}_{A_3} = \exp(\ln \hat{\lambda} + \hat{\beta}_{A_3}).
\]

The estimated lambda parameter of the baseline log-logistic distribution then is
\[
\hat{\lambda}_0 = \exp(\ln \hat{\lambda})
\]
so that
\[
\hat{\lambda}_{A_1} = \hat{\lambda}_0 \times \exp(\hat{\beta}_{A_1}) \\
\hat{\lambda}_{A_2} = \hat{\lambda}_0 \times \exp(\hat{\beta}_{A_2}) \\
\hat{\lambda}_{A_3} = \hat{\lambda}_0 \times \exp(\hat{\beta}_{A_3}).
\]

The estimated shape parameters of the baseline and the risk factor level log-logistic distributions are
\[
\hat{\alpha}_{A_1} \\
\hat{\alpha}_{A_2} \\
\hat{\alpha}_{A_3}.
\]

The SAS/IML program to fit a log-logistic regression model (shape parameter alters) to grouped survival data with staggered entry of policies appears in Appendix A.

4.7.5 Deriving of indices and risk scores from the log-logistic regression model

Once the parameters of the log-logistic baseline distribution and log-logistic risk factor level distributions have been estimated, estimated hazard and survivor functions, odds of a lapse, odds ratios and hazard ratios at time \( t \) can be calculated.

The odds ratio for risk factor level \( A_1 \) is the relative odds of a lapse at time \( t \) of a policy, with level \( A_1 \) characteristics, compared to a policy with the baseline characteristics. The odds ratios for the three risk factor levels result in a set of indices, showing the effect of each risk factor level on the baseline odds of a lapse at time \( t \).

The hazard ratio for risk factor level \( A_1 \) is the relative hazard rate of a lapse at time \( t \) of a policy, with level \( A_1 \) characteristics, compared to a policy with the baseline characteristics. The hazard ratios for the three risk factor levels result in a set of risk scores, showing the effect of each risk factor level on the baseline hazard rate of a lapse at time \( t \).

Percentiles of the four log-logistic survival distributions can also be estimated.
Log-logistic regression model

Shape remains constant

\[ \hat{h}_0(t) = \frac{\lambda_0 \cdot t^{\alpha - 1}}{1 + \lambda_0 \cdot t^\alpha} \]

\[ \hat{h}_{A_i}(t) = \frac{\lambda_{A_i} \cdot \alpha \cdot t^{\alpha - 1}}{1 + \lambda_{A_i} \cdot t^\alpha} \]

Estimated hazard function

\[ \hat{S}_0(t) = \frac{1}{1 + \lambda_0 \cdot t^\alpha} \]

\[ \hat{S}_{A_i}(t) = \frac{1}{1 + \lambda_{A_i} \cdot t^\alpha} \]

Estimated survivor function

Estimated odds of a lapse

\[ \frac{\hat{o}dd_{S_0}(t)}{\hat{S}_0(t)} = \hat{\lambda}_0 \cdot t^\alpha \]

\[ \frac{\hat{o}dd_{A_i}(t)}{\hat{S}_{A_i}(t)} = \hat{\lambda}_{A_i} \cdot t^\alpha \]

Estimated odds ratio or index

\[ \frac{\hat{o}dd_{ratio_{A_i}}(t)}{\hat{o}dd_{S_0}(t)} = \frac{\hat{\lambda}_{A_i} \cdot t^\alpha}{\hat{\lambda}_0 \cdot t^\alpha} \]

Estimated hazard ratio or risk score

\[ \frac{\hat{h}_{ratio_{A_i}}(t)}{\hat{h}_0(t)} = \frac{\hat{\lambda}_{A_i}}{\hat{\lambda}_0} \cdot \frac{(1 + \lambda_0 t^\alpha)}{(1 + \lambda_{A_i} t^\alpha)} \]

Estimated percentiles of lifetime distributions

baseline \( \hat{f}_p = \left( \frac{1}{\lambda_0} \cdot \frac{p}{100 - p} \right) \frac{1}{\hat{\alpha}} \)

pred. level \( \hat{f}_p = \left( \frac{1}{\lambda_{A_i}} \cdot \frac{p}{100 - p} \right) \frac{1}{\hat{\alpha}_i} \cdot (\text{index}) \frac{1}{\hat{\alpha}} \)

Shape parameter alters

\[ \hat{h}_0(t) = \frac{\lambda_0 \cdot \alpha \cdot t^{\alpha_0 - 1}}{1 + \lambda_0 \cdot t^{\alpha_0}} \]

\[ \hat{h}_{A_i}(t) = \frac{\lambda_{A_i} \cdot \alpha \cdot t^{\alpha_0 A_i - 1}}{1 + \lambda_{A_i} \cdot t^{\alpha_0 A_i}} \]

Estimated hazard function

\[ \hat{S}_0(t) = \frac{1}{1 + \lambda_0 \cdot t^{\alpha_0}} \]

\[ \hat{S}_{A_i}(t) = \frac{1}{1 + \lambda_{A_i} \cdot t^{\alpha_0 A_i}} \]

Estimated survivor function

Estimated odds of a lapse

\[ \frac{\hat{o}dd_{S_0}(t)}{\hat{S}_0(t)} = \hat{\lambda}_0 \cdot t^{\alpha_0} \]

\[ \frac{\hat{o}dd_{A_i}(t)}{\hat{S}_{A_i}(t)} = \hat{\lambda}_{A_i} \cdot t^{\alpha_0 A_i} \]

Estimated odds ratio or index

\[ \frac{\hat{o}dd_{ratio_{A_i}}(t)}{\hat{o}dd_{S_0}(t)} = \frac{\hat{\lambda}_{A_i} \cdot t^{\alpha_0 A_i}}{\hat{\lambda}_0 \cdot t^{\alpha_0}} \]

Estimated hazard ratio or risk score

\[ \frac{\hat{h}_{ratio_{A_i}}(t)}{\hat{h}_0(t)} = \frac{\hat{\lambda}_{A_i}}{\hat{\lambda}_0} \cdot \frac{(1 + \lambda_0 t^{\alpha_0})}{(1 + \lambda_{A_i} t^{\alpha_0 A_i})} \]

Estimated percentiles of lifetime distributions

baseline \( \hat{f}_p = \left( \frac{1}{\lambda_0} \cdot \frac{p}{100 - p} \right) \frac{1}{\hat{\alpha}_0} \)

pred. level \( \hat{f}_p = \left( \frac{1}{\lambda_{A_i}} \cdot \frac{p}{100 - p} \right) \frac{1}{\hat{\alpha}_i} \cdot (\text{index}) \frac{1}{\hat{\alpha}} \)

\( i = 1, 2, 3 \)
The estimated odds ratios are called \textbf{indices}. The index of a risk factor level shows the effect of this level on the baseline odds of a lapse. This effect is multiplicative on the baseline odds of a lapse and increases the baseline odds of a lapse (if the index > 1) or decreases the baseline odds of a lapse (if the index < 1).

The estimated hazard ratios are called \textbf{risk scores}. The risk score of a risk factor level shows the effect of this level on the baseline hazard rate of a lapse. This effect is multiplicative on the baseline hazard rate of a lapse and increases the baseline hazard rate of a lapse (if the risk score > 1) or decreases the baseline hazard rate of a lapse (if the risk score < 1).

Consider the risk factor \( A \) on three levels \( A_1, A_2 \) and \( A_3 \). Recall that the proportional odds model (POM) models the \textbf{odds of a lapse} at time \( t \) for a policy with risk vector \( Z = (Z_1, Z_2, \ldots, Z_p)' \) and regression coefficients \( \beta = (\beta_1, \beta_2, \ldots, \beta_p)' \)

\[
\Rightarrow \text{odds}_{A_l}(t|Z) = e^{\beta'Z} \cdot \text{odds}_0(t) \quad l = 1, 2, 3.
\]

This property of constant odds ratios over time only holds when the shape parameter of the log-logistic distributions of the baseline and risk factor levels remains constant.

Two dummy variables \( Z_{A_1} \) and \( Z_{A_2} \) are defined for levels \( A_1 \) and \( A_2 \) in such a way that the regression coefficient \( \beta_{A_3} \) of level \( A_3 \) is equal to \(- (\beta_{A_1} + \beta_{A_2})\). From the POM follows that

\[
\text{odds}_{A_1}(t|Z_{A_1} = 1, Z_{A_2} = 0) = e^{(\beta_{A_1} - \beta_{A_2})} \cdot \text{odds}_0(t) \Rightarrow \frac{\text{odds}_{A_1}(t|Z_{A_1} = 1, Z_{A_2} = 0)}{\text{odds}_0(t)} = e^{\beta_{A_1}}
\]

\[
\Rightarrow \text{odds ratio}_{A_1} = e^{\beta_{A_1}} = \frac{\lambda_{A_1}}{\lambda_0} \cdot \frac{t^\alpha}{t^\alpha} = \frac{\lambda_{A_1}}{\lambda_0}
\]

This means that for a \textbf{constant shape parameter} in the log-logistic distributions, the indices (estimated odds ratios) may be obtained also from the exponent of the estimated \( \beta \)-values in the log-logistic regression model.

\subsection{4.7.6 The Weibull regression model: staggered entry, the shape parameter remains constant}

In this model the effect of the risk factor is to alter the scale parameter \( \lambda \), while the shape parameter \( \alpha \) remains constant.

Equation 3.3 .11 can be extended to take covariates into account as follows:

\[
\ln (- \ln S(x)) = \ln \lambda \cdot 1 + \beta'Z + \alpha \cdot \ln x \quad (4.7 \cdot 16)
\]
Consider again a risk factor $A$ on three levels $A_1, A_2$ and $A_3$ for which two dummy variables $Z_{A_1}$ and $Z_{A_2}$ are defined. The staggered entry of policies occurs during four entry periods and $k$, the number of class intervals for the first entry group, equals seven.

Then Equation 4.7 .16 becomes

$$
\ln \left( - \ln S(x) \right) = \ln \lambda \cdot 1 + (\beta_{A_1}Z_{A_1} + \beta_{A_2}Z_{A_2}) + \alpha \cdot \ln x \quad (4.7 .17)
$$

or

$$
\ln \left( - \ln S(x) \right) = \ln \left( - \ln(1 - F(x)) \right) = \ln \left( - \ln(1 - \pi_S) \right)
$$

$$
= \ln \lambda \cdot \begin{pmatrix} 1 \\ 1 \\ 1 \\ 1 \\ 1 \\ 1 \\ 1 \end{pmatrix} + \beta_{A_1} \cdot \begin{pmatrix} 0 \\ 0 \\ 0 \\ 0 \\ 1 \\ 1 \\ 1 \end{pmatrix} + \beta_{A_2} \cdot \begin{pmatrix} 0 \\ 0 \\ 0 \\ 0 \\ -1 \\ -1 \\ -1 \end{pmatrix} + \alpha \cdot \begin{pmatrix} \ln x_1 \\ \ln x_2 \\ \ln x_3 \\ \ln x_4 \\ \ln x_1 \\ \ln x_2 \\ \ln x_3 \end{pmatrix}
$$

$$
= \begin{pmatrix} 1 & 1 & 0 \\ 1 & 1 & 0 \\ 1 & 1 & 0 \\ 1 & 1 & 0 \\ 1 & 0 & 1 \\ 1 & 0 & 1 \\ 1 & 0 & 1 \\ 1 & 0 & 1 \\ 1 & -1 & -1 \\ 1 & -1 & -1 \\ 1 & -1 & -1 \\ 1 & -1 & -1 \end{pmatrix} \begin{pmatrix} \ln \lambda \\ \beta_{A_1} \\ \beta_{A_2} \\ \alpha \end{pmatrix}
$$
\[ \Rightarrow \ln(-\ln(1 - \pi_S)) = X_1 \begin{pmatrix} \ln \lambda \\ \beta_{A_1} \\ \beta_{A_2} \\ \alpha \end{pmatrix} \]

Equation 4.7.18 is a linear model in the parameters \(\ln \lambda, \beta_{A_1}, \beta_{A_2}\) and \(\alpha\). This model is equivalent to

\[
\left( I - X_1(X_1'X_1)^{-1}X_1' \right) \cdot \ln(-\ln(1 - \pi_S)) = 0 \\
C \cdot \ln(-\ln(1 - \pi_S)) = 0 \\
g(\pi) = 0
\]

\(C\) is the projection matrix orthogonal to the columns of the design matrix \(X_1\). Note that \(CX_1 = 0\).

The function \(g(\pi) = 0\) satisfies the conditions of Proposition 1 and the estimation algorithm can be used to estimate the \(\lambda\)'s and \(\alpha\)'s of the Weibull distributions for the three levels of the risk factor \(A\).

To summarize, the constraints imposed by the Weibull distribution are specified by

\[
g(\pi) = C \cdot \ln \{- \ln(1 - \pi_S)\} = C \cdot \ln \{- \ln(1 - S \cdot \pi)\} = 0 \quad (4.7.19)
\]

with

\[
C = I - X_1(X_1'X_1)^{-1}X_1'. \quad (4.7.20)
\]

The derivative of \(g(\pi)\) with respect to \(\pi\) is

\[
G_{\pi} = \frac{\partial g(\pi)}{\partial \pi} = -C \cdot \text{diag} \left( \frac{1}{\ln(1 - \pi_S)} \right) \cdot \text{diag} \left( \frac{1}{1 - \pi_S} \right) \cdot S \quad (4.7.21)
\]

\[
= -C \cdot D_1^{-1} \cdot D_2^{-1} \cdot S \quad (4.7.22)
\]

where \(D_1\) and \(D_2\) are diagonal matrices with the elements of \(\ln(1 - \pi_S)\) and \((1 - \pi_S)\), respectively, on the main diagonal.
The estimated vector of probabilities is in this case

\[ \hat{\pi}_c = p - (G_V^T (G_B V G_B^T)^* C \ln \left( \frac{S \cdot p}{1 - S \cdot p} \right). \]  

with \( S \) and \( \hat{V} \), the estimated variance-covariance matrix, defined in section 4.7.2.

Since Equation 4.7.23 is still a function of the unknown parameter \( \pi \), the double iterative procedure must be implemented. Once the iterative procedure in Equation 4.7.23 has converged, the estimated parameters of the three Weibull distributions can be solved from

\[ \begin{pmatrix} \ln \hat{\lambda} \\ \hat{\beta}_{A_1} \\ \hat{\beta}_{A_2} \\ \hat{\alpha} \end{pmatrix} = \left( X_1' X_1 \right)^{-1} X_1' \ln (\ln(1 - S \cdot \hat{\pi}_c)) \]  

and \( \hat{\beta}_{A_1} = - \left( \hat{\beta}_{A_1} + \hat{\beta}_{A_2} \right) \).

The estimated lambda parameters of the three Weibull distributions for the three risk factor levels then are

\[ \hat{\lambda}_{A_1} = \exp(\ln \hat{\lambda} + \hat{\beta}_{A_1}) \]
\[ \hat{\lambda}_{A_2} = \exp(\ln \hat{\lambda} + \hat{\beta}_{A_2}) \]
\[ \hat{\lambda}_{A_3} = \exp(\ln \hat{\lambda} + \hat{\beta}_{A_3}). \]

The estimated lambda parameter of the baseline Weibull distribution then is

\[ \hat{\lambda}_0 = \exp(\ln \hat{\lambda}) \]

so that

\[ \hat{\lambda}_{A_1} = \hat{\lambda}_0 \times \exp(\hat{\beta}_{A_1}) \]
\[ \hat{\lambda}_{A_2} = \hat{\lambda}_0 \times \exp(\hat{\beta}_{A_2}) \]
\[ \hat{\lambda}_{A_3} = \hat{\lambda}_0 \times \exp(\hat{\beta}_{A_3}). \]

These four Weibull distributions all have the same estimated alpha parameter \( \hat{\alpha} \).

The SAS/IML program to fit a Weibull regression model (constant shape parameter) to grouped survival data with staggered entry of policies appears in Appendix A.

4.7.7 The Weibull regression model: staggered entry, the shape parameter alters

In this model the effect of the risk factor is to alter both the scale parameter \( \lambda \) and the shape parameter \( \alpha \).
Then Equation 4.7.16 becomes

\[
\ln(-\ln S(x)) = \ln(-\ln(1 - F(x))) = \ln(-\ln(1 - \pi_S))
\]

\[
\begin{pmatrix}
1 & 1 & 0 & \ln x_1 \\
1 & 1 & 0 & \ln x_2 \\
1 & 1 & 0 & \ln x_3 \\
1 & 1 & 0 & \ln x_4 \\
\end{pmatrix}
\begin{pmatrix}
\ln \lambda \\
\beta_{A_1} \\
\beta_{A_2} \\
\alpha_{A_1} \\
\alpha_{A_2} \\
\alpha_{A_3} \\
\end{pmatrix}
\]

\[
= \begin{pmatrix}
1 & 1 & 0 & \ln x_1 \\
1 & 1 & 0 & \ln x_2 \\
1 & 1 & 0 & \ln x_3 \\
1 & 1 & 0 & \ln x_4 \\
\end{pmatrix}
\begin{pmatrix}
\ln \lambda \\
\beta_{A_1} \\
\beta_{A_2} \\
\alpha_{A_1} \\
\alpha_{A_2} \\
\alpha_{A_3} \\
\end{pmatrix}
\]

\[
\Rightarrow \ln(-\ln(1 - \pi_S)) = X_1
\]

This is a linear model in the parameters \(\ln \lambda, \beta_{A_1}, \beta_{A_2}, \alpha_{A_1}, \alpha_{A_2}\) and \(\alpha_{A_3}\). This model is
equivalent to
\[
\left( I - X_1 (X_1' X_1)^{-1} X_1' \right) \cdot \ln \left( \frac{\ln(1 - \pi)}{\ln(1 - \pi_S)} \right) = 0 \\
\frac{C}{g(\pi)} \cdot \ln \left( \frac{\ln(1 - \pi)}{\ln(1 - \pi_S)} \right) = 0
\]

\(C\) is the projection matrix orthogonal to the columns of the design matrix \(X_1\). Note that \(CX_1 = 0\).

The function \(g(\pi) = 0\) satisfies the conditions of Proposition 1 and the estimation algorithm can be used to estimate the \(\lambda\)'s and \(\alpha\)'s of the Weibull distributions for the three levels of the risk factor \(A\).

To summarize, the constraints imposed by the Weibull distribution are specified by
\[
g(\pi) = C \cdot \ln \{ -\ln(1 - \pi_S) \} = C \cdot \ln \{ -\ln(1 - S \cdot \pi) \} = 0 \quad (4.7.25)
\]
with
\[
C = I - X_1 (X_1' X_1)^{-1} X_1' . \quad (4.7.26)
\]

The derivative of \(g(\pi)\) with respect to \(\pi\) is
\[
G_{\pi} = \frac{\partial g(\pi)}{\partial \pi} \\
= -C \cdot \text{diag} \left( \frac{1}{\ln(1 - \pi_S)} \right) \cdot \text{diag} \left( \frac{1}{1 - \pi_S} \right) \cdot S \quad (4.7.27)
\]
\[
= -C \cdot D_1^{-1} \cdot D_2^{-1} \cdot S \quad (4.7.28)
\]

where
\(D_1\) and \(D_2\) are diagonal matrices with the elements of \(\ln(1 - \pi_S)\) and \((1 - \pi_S)\), respectively, on the main diagonal.

The estimated vector of probabilities is in this case
\[
\tilde{\pi}_e = p - (G_{\pi} V)' (G_p V G_{\pi}')^* \cdot C \cdot \ln \left\{ \frac{S \cdot p}{1 - S \cdot p} \right\} . \quad (4.7.29)
\]
with \(S\) and \(V\), the estimated variance-covariance matrix, defined in section 4.7.2.

Since Equation 4.7.29 is still a function of the unknown parameter \(\pi\), the double iterative procedure must be implemented. Once the iterative procedure in Equation 4.7.29 has
converged, the estimated parameters of the three Weibull distributions can be solved from

\[
\begin{pmatrix}
\ln \lambda \\
\hat{\beta}_{A_1} \\
\hat{\beta}_{A_2} \\
\hat{\alpha}_{A_1} \\
\hat{\alpha}_{A_2} \\
\hat{\alpha}_{A_3}
\end{pmatrix} = \left( X_1' X_1 \right)^{-1} X_1' \cdot \ln \left\{ \frac{S \cdot \hat{\pi}_c}{1 - S \cdot \hat{\pi}_c} \right\}
\]

and \( \hat{\beta}_{A_3} = - (\hat{\beta}_{A_1} + \hat{\beta}_{A_2}) \).

The estimated lambda parameters of the three Weibull distributions for the three risk factor levels then are

\[
\begin{align*}
\hat{\lambda}_{A_1} &= \exp(\ln \lambda + \hat{\beta}_{A_1}) \\
\hat{\lambda}_{A_2} &= \exp(\ln \lambda + \hat{\beta}_{A_2}) \\
\hat{\lambda}_{A_3} &= \exp(\ln \lambda + \hat{\beta}_{A_3}).
\end{align*}
\]

The estimated lambda parameter of the baseline Weibull distribution then is

\( \hat{\lambda}_0 = \exp(\ln \lambda) \)

so that

\[
\begin{align*}
\hat{\lambda}_{A_1} &= \hat{\lambda}_0 \times \exp(\hat{\beta}_{A_1}) \\
\hat{\lambda}_{A_2} &= \hat{\lambda}_0 \times \exp(\hat{\beta}_{A_2}) \\
\hat{\lambda}_{A_3} &= \hat{\lambda}_0 \times \exp(\hat{\beta}_{A_3}).
\end{align*}
\]

The estimated shape parameters of the baseline and the risk factor level Weibull distributions are

\( \hat{\alpha}_{A_1} \)
\( \hat{\alpha}_{A_2} \)
\( \hat{\alpha}_{A_3} \).

The SAS/IML program to fit a Weibull regression model (shape parameter alters) to grouped survival data with staggered entry of policies appears in Appendix A.

### 4.7.8 Deriving of indices and risk scores from the Weibull regression model

Once the parameters of the Weibull baseline distribution and Weibull risk factor level distributions have been estimated, estimated hazard and survivor functions, odds of a lapse, odds ratios and hazard ratios at time \( t \) can be calculated.
The odds ratio for risk factor level $A_1$ is the relative odds of a lapse at time $t$ of a policy, with level $A_1$ characteristics, compared to a policy with the baseline characteristics. The odds ratios for the three risk factor levels result in a set of indices, showing the effect of each risk factor level on the baseline odds of a lapse at time $t$.

The hazard ratio for risk factor level $A_1$ is the relative hazard rate of a lapse at time $t$ of a policy with level $A_1$ characteristics, compared to a policy with the baseline characteristics. The hazard ratios for the three risk factor levels result in a set of risk scores, showing the effect of each risk factor level on the baseline hazard rate of a lapse at time $t$.

Percentiles of the four Weibull survival distributions can also be estimated.
Weibull regression model

**Shape remains constant**

**Estimated hazard function**
\[ \hat{h}_0(t) = \hat{\lambda}_0 \cdot \hat{\alpha} \cdot t^{\hat{\alpha} - 1} \]
\[ \hat{h}_{A_i}(t) = \hat{\lambda}_{A_i} \cdot \hat{\alpha} \cdot t^{\hat{\alpha} - 1} \]

**Estimated survivor function**
\[ \hat{S}_0(t) = \exp(-\hat{\lambda}_0 \cdot t^{\hat{\alpha}}) \]
\[ \hat{S}_{A_i}(t) = \exp(-\hat{\lambda}_{A_i} \cdot t^{\hat{\alpha}}) \]

**Estimated odds of a lapse**
\[ \hat{odds}_0(t) = \frac{1 - \hat{S}_0(t)}{\hat{S}_0(t)} = \exp(\hat{\lambda}_0 \cdot t^{\hat{\alpha} - 1}) \]
\[ \hat{odds}_{A_i}(t) = \frac{1 - \hat{S}_{A_i}(t)}{\hat{S}_{A_i}(t)} = \exp(\hat{\lambda}_{A_i} \cdot t^{\hat{\alpha} - 1}) \]

**Estimated odds ratio or index**
\[ \hat{oddsratio}_{A_i}(t) = \frac{\hat{odds}_{A_i}(t)}{\hat{odds}_0(t)} = \frac{\exp(\hat{\lambda}_{A_i} \cdot t^{\hat{\alpha} - 1})}{\exp(\hat{\lambda}_0 \cdot t^{\hat{\alpha} - 1})} \]

**Estimated hazard ratio or risk score**
\[ \hat{hazardratio}_{A_i}(t) = \frac{\hat{h}_{A_i}(t)}{\hat{h}_0(t)} = \frac{\hat{\lambda}_{A_i} \cdot \hat{\alpha} \cdot t^{\hat{\alpha} - 1}}{\hat{\lambda}_0 \cdot \hat{\alpha} \cdot t^{\hat{\alpha} - 1}} \]

**Estimated percentiles of lifetime distributions**
baseline \( \hat{t}_p = \left( \frac{1}{\hat{\lambda}_0} \cdot \ln \frac{100}{100 - p} \right)^{\frac{1}{\hat{\alpha}}} \)

\[ \text{pred. level} \hat{t}_p = \left( \frac{1}{\hat{\lambda}_{A_i}} \cdot \ln \frac{100}{100 - p} \right)^{\frac{1}{\hat{\alpha}}} \]
= baseline \( \hat{t}_p \) \cdot \text{(risk score)}^{\frac{1}{\hat{\alpha}}} \]

**Shape parameter alters**

**Estimated hazard function**
\[ \hat{h}_0(t) = \hat{\lambda}_0 \cdot \hat{\alpha}_0 \cdot t^{\hat{\alpha}_0 - 1} \]
\[ \hat{h}_{A_i}(t) = \hat{\lambda}_{A_i} \cdot \hat{\alpha}_{A_i} \cdot t^{\hat{\alpha}_{A_i} - 1} \]

**Estimated survivor function**
\[ \hat{S}_0(t) = \exp(-\hat{\lambda}_0 \cdot t^{\hat{\alpha}_0}) \]
\[ \hat{S}_{A_i}(t) = \exp(-\hat{\lambda}_{A_i} \cdot t^{\hat{\alpha}_{A_i}}) \]

**Estimated odds of a lapse**
\[ \hat{odds}_0(t) = \frac{1 - \hat{S}_0(t)}{\hat{S}_0(t)} = \exp(\hat{\lambda}_0 \cdot t^{\hat{\alpha}_0 - 1}) \]
\[ \hat{odds}_{A_i}(t) = \frac{1 - \hat{S}_{A_i}(t)}{\hat{S}_{A_i}(t)} = \exp(\hat{\lambda}_{A_i} \cdot t^{\hat{\alpha}_{A_i} - 1}) \]

**Estimated odds ratio or index**
\[ \hat{oddsratio}_{A_i}(t) = \frac{\hat{odds}_{A_i}(t)}{\hat{odds}_0(t)} = \frac{\exp(\hat{\lambda}_{A_i} \cdot t^{\hat{\alpha}_{A_i} - 1})}{\exp(\hat{\lambda}_0 \cdot t^{\hat{\alpha}_0 - 1})} \]

**Estimated hazard ratio or risk score**
\[ \hat{hazardratio}_{A_i}(t) = \frac{\hat{h}_{A_i}(t)}{\hat{h}_0(t)} = \frac{\hat{\lambda}_{A_i} \cdot \hat{\alpha}_{A_i} \cdot t^{\hat{\alpha}_{A_i} - 1}}{\hat{\lambda}_0 \cdot \hat{\alpha}_0 \cdot t^{\hat{\alpha}_0 - 1}} \]

**Estimated percentiles of lifetime distributions**
baseline \( \hat{t}_p = \left( \frac{1}{\hat{\lambda}_0} \cdot \ln \frac{100}{100 - p} \right)^{\frac{1}{\hat{\alpha}_0}} \)

\[ \text{pred. level} \hat{t}_p = \left( \frac{1}{\hat{\lambda}_{A_i}} \cdot \ln \frac{100}{100 - p} \right)^{\frac{1}{\hat{\alpha}_{A_i}}} \]
= baseline \( \hat{t}_p \) \cdot \text{(risk score)}^{\frac{1}{\hat{\alpha}_{A_i}}} \]

\( i = 1, 2, 3 \)
The estimated hazard ratios are called risk scores. The risk score of a risk factor level shows the effect of this level on the baseline hazard rate of a lapse. This effect is multiplicative on the baseline hazard rate of a lapse and increases the baseline hazard rate of a lapse (if the risk score > 1) or decreases the baseline hazard rate of a lapse (if the risk score < 1).

The estimated odds ratios are called indices. The index of a risk factor level shows the effect of this level on the baseline odds of a lapse. This effect is multiplicative on the baseline odds of a lapse and increases the baseline odds of a lapse (if the index > 1) or decreases the baseline odds of a lapse (if the index < 1).

Consider the risk factor $A$ on three levels $A_1, A_2$ and $A_3$. Recall that the proportional hazards model (PHM) models $h(t|Z)$, the hazard rate of a lapse at time $t$ for a policy with risk vector $Z = (Z_1, Z_2, ..., Z_p)'$ and regression coefficients $\beta = (\beta_1, \beta_2, ..., \beta_p)'$

$$\Rightarrow h_{A_l}(t|Z) = e^{\beta'Z} \cdot h_0(t) \quad l = 1, 2, 3$$

This property of constant hazard ratios over time only holds when the shape parameter of the Weibull distributions of the baseline and risk factor levels remains constant.

Two dummy variables $Z_{A_1}$ and $Z_{A_2}$ are defined for levels $A_1$ and $A_2$ in such a way that the regression coefficient $\beta_{A_3}$ of level $A_3$ is equal to $-(\beta_{A_1} + \beta_{A_2})$. From the PHM follows that

$$h_{A_1}(t|Z_{A_1} = 1, Z_{A_2} = 0) = e^{(\beta_{A_1} + \beta_{A_2} \cdot 0)} \cdot h_0(t) \Rightarrow \frac{h_{A_1}(t|Z_{A_1} = 1, Z_{A_2} = 0)}{h_0(t)} = e^{\beta_{A_1}} \Rightarrow \text{hazardratio}_{A_1} = e^{\hat{\beta}_{A_1}} = \frac{\hat{\lambda}_{A_1} \cdot \hat{\alpha} \cdot t^{\hat{\alpha} - 1}}{\hat{\lambda}_0 \cdot \hat{\alpha} \cdot t^{\hat{\alpha} - 1}} = \frac{\hat{\lambda}_{A_1}}{\hat{\lambda}_0}$$

This means that for a constant shape parameter in the Weibull distributions, the risk scores (estimated hazard ratios) may be also obtained from the exponent of the estimated $\beta$-values in the Weibull regression model.

4.7.9 The fitting of a regression model with a continuous risk factor

Consider a continuous risk factor that can be categorized into three groups. Define the ordinal covariate $Z$ that takes on the values $z=1$ for the first group, $z=2$ for the second group and $z=3$ for the third group. Denote a vector of two's by $2$ and a vector of three's by $3$. 
The log-logistic regression model with a continuous risk factor

The log-logistic regression model that models \( \ln(\text{odds}) \) is then

\[
\ln \left( \frac{1 - S(x)}{S(x)} \right) = \ln \lambda \cdot 1 + \beta \cdot z + \alpha \cdot \ln x
\]

or

\[
\ln \left( \frac{1 - S(x)}{S(x)} \right) = \ln \left( \frac{F(x)}{1 - F(x)} \right) = \ln \left( \frac{\pi_s}{1 - \pi_s} \right) = \ln (\pi_s) - \ln (1 - \pi_s)
\]

\[
\begin{pmatrix}
1 \\
1 \\
1 \\
1 \\
1
\end{pmatrix}
\begin{pmatrix}
\ln x_1 \\
\ln x_2 \\
\ln x_3 \\
\ln x_4
\end{pmatrix}
= \ln \lambda \cdot
\begin{pmatrix}
1 \\
1 \\
1 \\
1
\end{pmatrix}
\begin{pmatrix}
\ln x_1 \\
\ln x_2 \\
\ln x_3 \\
\ln x_4
\end{pmatrix}
+ \alpha \cdot
\begin{pmatrix}
1 \\
1 \\
1 \\
1
\end{pmatrix}
\begin{pmatrix}
\ln x_1 \\
\ln x_2 \\
\ln x_3 \\
\ln x_4
\end{pmatrix}
+ \beta \cdot
\begin{pmatrix}
1 \\
1 \\
1 \\
1
\end{pmatrix}
\begin{pmatrix}
\ln x_1 \\
\ln x_2 \\
\ln x_3 \\
\ln x_4
\end{pmatrix}
\]

\[
= \begin{pmatrix}
1 \\
1 \\
1 \\
1
\end{pmatrix}
\begin{pmatrix}
\ln x_1 \\
\ln x_2 \\
\ln x_3 \\
\ln x_4
\end{pmatrix}
\begin{pmatrix}
1 \\
1 \\
1 \\
1
\end{pmatrix}
\begin{pmatrix}
\ln \lambda \\
\alpha \\
\beta
\end{pmatrix}
\]

\[
= \begin{pmatrix}
1 \\
1 \\
1 \\
1
\end{pmatrix}
\begin{pmatrix}
\ln x_1 \\
\ln x_2 \\
\ln x_3 \\
\ln x_4
\end{pmatrix}
\begin{pmatrix}
1 \\
1 \\
1 \\
1
\end{pmatrix}
\begin{pmatrix}
\ln \lambda \\
\alpha \\
\beta
\end{pmatrix}
\]
\[ \ln \left( \frac{\pi_S}{1 - \pi_S} \right) = X_1 \cdot \begin{pmatrix} \ln \lambda \\ \alpha \\ \beta \end{pmatrix} \quad (4.7.32) \]

Equation 4.7.32 is a linear model in the parameters \( \ln \lambda \), \( \alpha \) and \( \beta \).

By proceeding in a similar way as in section 4.7.3, the estimated parameters of the log-logistic distributions for the three risk factor groups can be solved from

\[ \begin{pmatrix} \ln \lambda \\ \hat{\alpha} \\ \hat{\beta} \end{pmatrix} = (X_1'X_1)^{-1}X_1' \cdot \ln \left\{ \frac{S \cdot \hat{\pi}_c}{1 - S \cdot \hat{\pi}_c} \right\} \quad (4.7.33) \]

with \( S \) and \( \hat{\pi}_c \) defined in section 4.7.3.

The estimated lambda parameters of these three log-logistic distributions then are

\[ \hat{\lambda}_{Z=1} = \exp(\ln \lambda + \hat{\beta} \cdot 1) \]
\[ \hat{\lambda}_{Z=2} = \exp(\ln \lambda + \hat{\beta} \cdot 2) \]
\[ \hat{\lambda}_{Z=3} = \exp(\ln \lambda + \hat{\beta} \cdot 3). \]

The estimated lambda parameter of the baseline log-logistic distribution then is

\[ \hat{\lambda}_0 = \exp(\ln \lambda) \]

so that

\[ \hat{\lambda}_{Z=1} = \hat{\lambda}_0 \times \exp(\hat{\beta} \cdot 1) \]
\[ \hat{\lambda}_{Z=2} = \hat{\lambda}_0 \times \exp(\hat{\beta} \cdot 2) \]
\[ \hat{\lambda}_{Z=3} = \hat{\lambda}_0 \times \exp(\hat{\beta} \cdot 3). \]

These four log-logistic distributions all have the same estimated alpha parameter \( \hat{\alpha} \).

The above procedure can also be applied when other continuous values of \( z \), instead of the values 1,2,3, are used, for example the midpoints of the risk factor groupings. An application will be discussed in chapter 5.

The SAS/IML program to fit a log-logistic regression model with one continuous risk factor (constant shape parameter) to grouped survival data with staggered entry of policies appears in Appendix A.
The Weibull regression model with a continuous risk factor

The Weibull regression model is

$$\ln (-\ln S(x)) = \ln \lambda \cdot 1 + \beta \cdot z + \alpha \cdot \ln x$$

or

$$\ln (-\ln S(x)) = \ln (-\ln (1 - F(x))) = \ln (-\ln (1 - \pi_s))$$

$$= \ln \lambda \cdot \begin{pmatrix} 1 \\ 1 \\ 1 \\ 1 \\ 1 \end{pmatrix} + \alpha \cdot \begin{pmatrix} \ln x_1 \\ \ln x_2 \\ \ln x_3 \\ \ln x_4 \\ \ln x_5 \end{pmatrix} + \beta \cdot \begin{pmatrix} \ln x_1 \\ \ln x_2 \\ \ln x_3 \\ \ln x_4 \end{pmatrix}$$

$$= \begin{pmatrix} 1 \ln x_1 & 1 \\ 1 \ln x_2 & 1 \\ 1 \ln x_3 & 1 \\ 1 \ln x_4 & 1 \\ 1 \ln x_5 & 1 \end{pmatrix} \cdot \begin{pmatrix} \ln \lambda \\ \alpha \\ \beta \end{pmatrix}$$
\[ \Rightarrow \ln \left( -\ln(1 - \pi_s) \right) = X_1 \cdot \begin{pmatrix} \ln \lambda \\ \alpha \\ \beta \end{pmatrix} \] (4.7.35)

Equation 4.7.35 is a linear model in the parameters \( \ln \lambda, \alpha \) and \( \beta \).

By proceeding in a similar way as in section 4.7.6, the estimated parameters of the Weibull distributions for the three risk factor groups can be solved from

\[
\begin{pmatrix} \hat{\ln \lambda} \\ \hat{\alpha} \\ \hat{\beta} \end{pmatrix} = (X_1'X_1)^{-1}X_1' \cdot \ln \left\{ \frac{S \cdot \hat{\pi}_c}{1 - S \cdot \hat{\pi}_c} \right\} \] (4.7.36)

with \( S \) and \( \hat{\pi}_c \) defined in section 4.7.6.

The estimated lambda parameters of these three Weibull distributions then are

\[
\hat{\lambda}_{Z=1} = \exp(\ln \lambda + \hat{\beta} \times 1) \\
\hat{\lambda}_{Z=2} = \exp(\ln \lambda + \hat{\beta} \times 2) \\
\hat{\lambda}_{Z=3} = \exp(\ln \lambda + \hat{\beta} \times 3).
\]

The estimated lambda parameter of the baseline Weibull distribution then is

\[ \hat{\lambda}_0 = \exp(\ln \lambda) \]

so that

\[
\hat{\lambda}_{Z=1} = \hat{\lambda}_0 \times \exp(\hat{\beta} \times 1) \\
\hat{\lambda}_{Z=2} = \hat{\lambda}_0 \times \exp(\hat{\beta} \times 2) \\
\hat{\lambda}_{Z=3} = \hat{\lambda}_0 \times \exp(\hat{\beta} \times 3).
\]

These four Weibull distributions all have the same estimated alpha parameter \( \hat{\alpha} \).

The above procedure can also be applied when other continuous values of \( z \), instead of the values 1,2,3, are used, for example the midpoints of the risk factor groupings. An application will be discussed in chapter 5.

The SAS/IML program to fit a Weibull regression model with one continuous risk factor (constant shape parameter) to grouped survival data with staggered entry of policies appears in Appendix A.
4.7.10 Notation for a regression model with two risk factors at staggered entry

Consider two risk factors $A$ and $B$, each on three levels $A_1, A_2$ and $A_3$ and $B_1, B_2$ and $B_3$ respectively. Staggered entry of policies occur during four different entry periods and $k$, the number of class intervals for the first entry group, is equal to seven.

$p_{ilm}$ is the relative frequency vector for the $i^{th}$ entry group, the $l^{th}$ risk factor $A$ level and the $m^{th}$ risk factor $B$ level corresponding to $n_{ilm}p_{ilm}$ being multinomial $(n_{ilm}; \pi_{ilm})$ distributed $i = 1, 2, 3$ and $l = 1, 2, 3$ and $m = 1, 2, 3.$

$p_{1lm} = (p_{1lm,1}, p_{1lm,2}, p_{1lm,3}, p_{1lm,4}, p_{1lm,5}, p_{1lm,6}, p_{1lm,7})'$ is a $7 \times 1$ relative frequency vector

$p_{2lm} = (p_{2lm,1}, p_{2lm,2}, p_{2lm,3}, p_{2lm,4}, p_{2lm,5}, p_{2lm,6})'$ is a $6 \times 1$ relative frequency vector

$p_{3lm} = (p_{3lm,1}, p_{3lm,2}, p_{3lm,3}, p_{3lm,4}, p_{3lm,5})'$ is a $5 \times 1$ relative frequency vector

$p_{4lm} = (p_{4lm,1}, p_{4lm,2}, p_{4lm,3}, p_{4lm,4})'$ is a $4 \times 1$ relative frequency vector

and

$\pi_{1lm} = (\pi_{1lm,1}, \pi_{1lm,2}, \pi_{1lm,3}, \pi_{1lm,4}, \pi_{1lm,5}, \pi_{1lm,6}, \pi_{1lm,7})'$ is a $7 \times 1$ probability vector

$\pi_{2lm} = (\pi_{2lm,1}, \pi_{2lm,2}, \pi_{2lm,3}, \pi_{2lm,4}, \pi_{2lm,5}, \pi_{2lm,6})'$ is a $6 \times 1$ probability vector

$\pi_{3lm} = (\pi_{3lm,1}, \pi_{3lm,2}, \pi_{3lm,3}, \pi_{3lm,4}, \pi_{3lm,5})'$ is a $5 \times 1$ probability vector

$\pi_{4lm} = (\pi_{4lm,1}, \pi_{4lm,2}, \pi_{4lm,3}, \pi_{4lm,4})'$ is a $4 \times 1$ probability vector

The vectors $x_i$, $i = 1, 2, 3, 4$ of upper class boundaries for the $i^{th}$ entry group are

\[
   x_1 = \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \\ x_5 \\ x_6 \end{pmatrix} \quad x_2 = \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \\ x_5 \end{pmatrix} \quad x_3 = \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{pmatrix} \quad \text{and} \quad x_4 = \begin{pmatrix} x_1 \\ x_2 \\ x_3 \end{pmatrix}.
\]

The number of entries per cell in the cross tabulation of entry period and risk factors $A$ and $B$ can be summarized in table 4.2.
Table 4.2: Number of entries per cell in cross table of entry period and risk factors $A$ and $B$

Matrix $S$ is now a $(54 \times 3) \times (66 \times 3) = 162 \times 198$ matrix and is defined as

$$S = \begin{pmatrix} S_{11} \\ S_{12} \\ S_{13} \\ S_{21} \\ S_{22} \\ S_{23} \\ S_{31} \\ S_{32} \\ S_{33} \end{pmatrix}$$

where $S_{lm} = \text{block}(S_1, S_2, S_3, S_4)$ is a $18 \times 22$ matrix of the form

$$S_{lm} = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \end{pmatrix}$$

The variance-covariance matrix $V$ to be used is the estimated variance-covariance matrix of the multinomial distribution for each combination of entry period and risk factor $A$. 

level and risk factor $B$ level.

\[ \tilde{V} = \text{block}(\tilde{V}_{11}, \tilde{V}_{12}, \tilde{V}_{13}, \tilde{V}_{21}, \tilde{V}_{22}, \tilde{V}_{23}, \tilde{V}_{31}, \tilde{V}_{32}, \tilde{V}_{33}) \]

where

\[ \tilde{V}_{lm} = \text{block}(\tilde{V}_{1,m}, \tilde{V}_{2,m}, \tilde{V}_{3,m}, \tilde{V}_{4,m}) \quad l = 1, 2, 3 \quad \text{and} \quad m = 1, 2, 3 \]

and

\[ \tilde{v}_{i,lm} = \frac{1}{n_{ilm}} \left[ \text{diag}(p_{ilm}) - p_{ilm}^{-1} \right] \quad i = 1, 2, 3, 4 \quad \text{and} \quad l = 1, 2, 3 \quad \text{and} \quad m = 1, 2, 3. \]

Note that $\tilde{V}_{1,lm}$ is a $21 \times 21$, $\tilde{V}_{2,lm}$ is a $18 \times 18$, $\tilde{V}_{3,lm}$ is a $15 \times 15$ and $\tilde{V}_{4,lm}$ is a $12 \times 12$ matrix so that $\tilde{V}_{lm}$ is a $66 \times 66$ matrix and $\tilde{V}$ is a $198 \times 198$ matrix.

4.7.11 **The log-logistic regression model with two risk factors at staggered entry**

In this model the effect of the risk factors is to alter the scale parameter $\lambda$, while the shape parameter $\alpha$ remains constant.

Consider a risk factor $A$ on three levels $A_1, A_2$ and $A_3$ and another risk factor $B$ on three levels $B_1, B_2$ and $B_3$. Two dummy variables $Z_{A_1}$ and $Z_{A_2}$ are defined for levels $A_1$ and $A_2$ in such a way that the regression coefficient $\beta_{A_3}$ of level $A_3$ is equal to $-(\beta_{A_1} + \beta_{A_2})$, that means \( \sum_{k=1}^{3} \beta_{A_k} = 0 \). Similarly two dummy variables $Z_{B_1}$ and $Z_{B_2}$ are defined for levels $B_1$ and $B_2$ in such a way that the regression coefficient $\beta_{B_3}$ of level $B_3$ is equal to $-(\beta_{B_1} + \beta_{B_2})$, that means \( \sum_{k=1}^{3} \beta_{B_k} = 0 \).

The log-logistic regression model that models \( \ln(\text{odds}) \) then is

\[
\ln \left( \frac{1 - S(x)}{S(x)} \right) = \ln \lambda \cdot 1 + (\beta_{A_1} Z_{A_1} + \beta_{A_2} Z_{A_2}) + (\beta_{B_1} Z_{B_1} + \beta_{B_2} Z_{B_2}) + \alpha \cdot \ln x
\]

or

\[
\ln \left( \frac{1 - S(x)}{S(x)} \right) = \ln \left( \frac{F(x)}{1 - F(x)} \right) = \ln \left( \frac{\pi_S}{1 - \pi_S} \right) = \ln(\pi_S) - \ln (1 - \pi_S)
\]
\begin{align*}
\ln \lambda &= \ln \sigma_1 \\
&+ \beta_{A1} \cdot 1 \\
&+ \beta_{A2} \cdot 1 \\
&+ \beta_{E1} \cdot 1 \\
&+ \beta_{B2} \cdot 1 + \alpha \cdot 1
\end{align*}
\[
\begin{pmatrix}
1 & 1 & 0 & 1 & 0 & \ln x_1 \\
1 & 1 & 0 & 1 & 0 & \ln x_2 \\
1 & 1 & 0 & 1 & 0 & \ln x_3 \\
1 & 1 & 0 & 1 & 0 & \ln x_4 \\
1 & 1 & 0 & 0 & 1 & \ln x_1 \\
1 & 1 & 0 & 0 & 1 & \ln x_2 \\
1 & 1 & 0 & 0 & 1 & \ln x_3 \\
1 & 1 & 0 & 0 & 1 & \ln x_4 \\
1 & 1 & 0 & -1 & -1 & \ln x_1 \\
1 & 1 & 0 & -1 & -1 & \ln x_2 \\
1 & 1 & 0 & -1 & -1 & \ln x_3 \\
1 & 1 & 0 & -1 & -1 & \ln x_4 \\
1 & 0 & 1 & 1 & 0 & \ln x_1 \\
1 & 0 & 1 & 1 & 0 & \ln x_2 \\
1 & 0 & 1 & 1 & 0 & \ln x_3 \\
1 & 0 & 1 & 1 & 0 & \ln x_4 \\
1 & 0 & 1 & 0 & 1 & \ln x_1 \\
1 & 0 & 1 & 0 & 1 & \ln x_2 \\
1 & 0 & 1 & 0 & 1 & \ln x_3 \\
1 & 0 & 1 & 0 & 1 & \ln x_4 \\
1 & 0 & 1 & -1 & -1 & \ln x_1 \\
1 & 0 & 1 & -1 & -1 & \ln x_2 \\
1 & 0 & 1 & -1 & -1 & \ln x_3 \\
1 & 0 & 1 & -1 & -1 & \ln x_4 \\
1 & -1 & -1 & 1 & 0 & \ln x_1 \\
1 & -1 & -1 & 1 & 0 & \ln x_2 \\
1 & -1 & -1 & 1 & 0 & \ln x_3 \\
1 & -1 & -1 & 1 & 0 & \ln x_4 \\
1 & -1 & -1 & 0 & 1 & \ln x_1 \\
1 & -1 & -1 & 0 & 1 & \ln x_2 \\
1 & -1 & -1 & 0 & 1 & \ln x_3 \\
1 & -1 & -1 & 0 & 1 & \ln x_4 \\
1 & -1 & -1 & 0 & 1 & \ln x_1 \\
1 & -1 & -1 & 0 & 1 & \ln x_2 \\
1 & -1 & -1 & -1 & -1 & \ln x_3 \\
1 & -1 & -1 & -1 & -1 & \ln x_4
\end{pmatrix}
\Rightarrow \ln \left( \frac{\pi_S}{1 - \pi_S} \right) = X_1 \cdot \begin{pmatrix}
\ln \lambda \\
\beta_{A_1} \\
\beta_{A_2} \\
\beta_{B_1} \\
\beta_{B_2} \\
\alpha
\end{pmatrix}
\Rightarrow \ln \left( \frac{\pi_S}{1 - \pi_S} \right) = X_1 \cdot \begin{pmatrix}
\ln \lambda \\
\beta_{A_1} \\
\beta_{A_2} \\
\beta_{B_1} \\
\beta_{B_2} \\
\alpha
\end{pmatrix}
This model is a linear model in the parameters $\ln \lambda$, $\beta_{A_1}$, $\beta_{A_2}$, $\beta_{B_1}$, $\beta_{B_2}$ and $\alpha$.

By proceeding in a similar way as in section 4.7.3, the estimated parameters of the log-logistic distributions for the nine combinations of risk factor $A$ levels and risk factor $B$ levels can be solved from

$$
\begin{pmatrix}
\ln \lambda \\
\hat{\beta}_{A_1} \\
\hat{\beta}_{A_2} \\
\hat{\beta}_{B_1} \\
\hat{\beta}_{B_2} \\
\hat{\alpha}
\end{pmatrix} = (X_1' X_1)^{-1} X_1' \cdot \ln \left\{ \frac{S \cdot \hat{\pi}_c}{1 - S \cdot \hat{\pi}_c} \right\}
$$

with $\hat{\pi}_c = p - (G_\pi V)' (G_\pi V G_\pi')^* \cdot C \cdot \ln \left\{ \frac{S \cdot p}{1 - S \cdot p} \right\}$ where $S$, $V$ and $p$ are defined in section 4.7.10

Note that $\hat{\beta}_{A_3} = -\left(\hat{\beta}_{A_1} + \hat{\beta}_{A_2}\right)$ and $\hat{\beta}_{B_3} = -\left(\hat{\beta}_{B_1} + \hat{\beta}_{B_2}\right)$.

The estimated lambda parameters of the nine log-logistic distributions for the nine combinations of risk factor $A$ levels and risk factor $B$ levels then are

$$
\begin{align*}
\hat{\lambda}_{A_1B_1} &= \exp(\ln \lambda + \hat{\beta}_{A_1} + \hat{\beta}_{B_1}) \\
\hat{\lambda}_{A_1B_2} &= \exp(\ln \lambda + \hat{\beta}_{A_1} + \hat{\beta}_{B_2}) \\
\hat{\lambda}_{A_1B_3} &= \exp(\ln \lambda + \hat{\beta}_{A_1} + \hat{\beta}_{B_3}) \\
\hat{\lambda}_{A_2B_1} &= \exp(\ln \lambda + \hat{\beta}_{A_2} + \hat{\beta}_{B_1}) \\
\hat{\lambda}_{A_2B_2} &= \exp(\ln \lambda + \hat{\beta}_{A_2} + \hat{\beta}_{B_2}) \\
\hat{\lambda}_{A_2B_3} &= \exp(\ln \lambda + \hat{\beta}_{A_2} + \hat{\beta}_{B_3}) \\
\hat{\lambda}_{A_3B_1} &= \exp(\ln \lambda + \hat{\beta}_{A_3} + \hat{\beta}_{B_1}) \\
\hat{\lambda}_{A_3B_2} &= \exp(\ln \lambda + \hat{\beta}_{A_3} + \hat{\beta}_{B_2}) \\
\hat{\lambda}_{A_3B_3} &= \exp(\ln \lambda + \hat{\beta}_{A_3} + \hat{\beta}_{B_3}).
\end{align*}
$$

The estimated lambda parameter of the baseline log-logistic distribution then is

$$
\hat{\lambda}_0 = \exp(\ln \lambda)
$$
so that

\[
\begin{align*}
\lambda_{A_1 B_1} &= \lambda_0 \times \text{index}_{A_1} \times \text{index}_{B_1} \\
\lambda_{A_1 B_2} &= \lambda_0 \times \text{index}_{A_1} \times \text{index}_{B_2} \\
\lambda_{A_1 B_3} &= \lambda_0 \times \text{index}_{A_1} \times \text{index}_{B_3} \\
\lambda_{A_2 B_1} &= \lambda_0 \times \text{index}_{A_2} \times \text{index}_{B_1} \\
\lambda_{A_2 B_2} &= \lambda_0 \times \text{index}_{A_2} \times \text{index}_{B_2} \\
\lambda_{A_2 B_3} &= \lambda_0 \times \text{index}_{A_2} \times \text{index}_{B_3} \\
\lambda_{A_3 B_1} &= \lambda_0 \times \text{index}_{A_3} \times \text{index}_{B_1} \\
\lambda_{A_3 B_2} &= \lambda_0 \times \text{index}_{A_3} \times \text{index}_{B_2} \\
\lambda_{A_3 B_3} &= \lambda_0 \times \text{index}_{A_3} \times \text{index}_{B_3}.
\end{align*}
\]

These ten log-logistic distributions all have the same estimated alpha parameter \( \hat{\alpha} \).

The SAS/IML program to fit a log-logistic regression model with two categorical risk factors (constant shape parameter) to grouped survival data with staggered entry of policies appears in Appendix A.

### 4.7.12 The Weibull regression model with two risk factors at staggered entry

In this model the effect of the risk factors is to alter the scale parameter \( \lambda \), while the shape parameter \( \alpha \) remains constant.

Consider again a risk factor \( A \) on three levels \( A_1, A_2 \) and \( A_3 \) and another risk factor \( B \) on three levels \( B_1, B_2 \) and \( B_3 \). Two dummy variables \( Z_{A_1} \) and \( Z_{A_2} \) are defined for levels \( A_1 \) and \( A_2 \) in such a way that the regression coefficient \( \beta_{A_3} \) of level \( A_3 \) is equal to \( -(\beta_{A_1} + \beta_{A_2}) \), that means \( \sum_{k=1}^{3} \beta_{A_k} = 0 \). Similarly two dummy variables \( Z_{B_1} \) and \( Z_{B_2} \) are defined for levels \( B_1 \) and \( B_2 \) in such a way that the regression coefficient \( \beta_{B_3} \) of level \( B_3 \) is equal to \( -(\beta_{B_1} + \beta_{B_2}) \), that means \( \sum_{k=1}^{3} \beta_{B_k} = 0 \).

The Weibull regression model then is

\[
\ln (-\ln S(x)) = \ln \lambda \cdot 1 + (\beta_{A_1} Z_{A_1} + \beta_{A_2} Z_{A_2}) + (\beta_{B_1} Z_{B_1} + \beta_{B_2} Z_{B_2}) + \alpha \cdot \ln x
\]

or

\[
\ln (-\ln S(x)) = \ln \left( \frac{F(x)}{1 - F(x)} \right) = \ln \left( \frac{\pi_S}{1 - \pi_S} \right) = \ln (\pi_S) - \ln (1 - \pi_S)
\]
\[
\begin{align*}
&= \ln \lambda \cdot \\
&\quad + \beta_{A_1} \cdot \\
&\quad + \beta_{A_2} \cdot \\
&\quad + \beta_{B_1} \cdot \\
&\quad + \beta_{B_2} \cdot \\
&\quad + \alpha \cdot \\
\end{align*}
\]
\[\ln(-\ln S(x)) = \begin{pmatrix}
1 & 1 & 0 & 1 & 0 & \ln x_1 \\
1 & 1 & 0 & 1 & 0 & \ln x_2 \\
1 & 1 & 0 & 1 & 0 & \ln x_3 \\
1 & 1 & 0 & 1 & 0 & \ln x_4 \\
1 & 1 & 0 & 0 & 0 & 1 & \ln x_2 \\
1 & 1 & 0 & 0 & 0 & 1 & \ln x_3 \\
1 & 1 & 0 & 0 & 0 & 1 & \ln x_4 \\
1 & 1 & 0 & -1 & -1 & \ln x_1 \\
1 & 1 & 0 & -1 & -1 & \ln x_2 \\
1 & 1 & 0 & -1 & -1 & \ln x_3 \\
1 & 1 & 0 & -1 & -1 & \ln x_4 \\
1 & 0 & 1 & 1 & 0 & \ln x_1 \\
1 & 0 & 1 & 1 & 0 & \ln x_2 \\
1 & 0 & 1 & 1 & 0 & \ln x_3 \\
1 & 0 & 1 & 1 & 0 & \ln x_4 \\
1 & 0 & 1 & 0 & 0 & 1 & \ln x_1 \\
1 & 0 & 1 & 0 & 0 & 1 & \ln x_2 \\
1 & 0 & 1 & 0 & 0 & 1 & \ln x_3 \\
1 & 0 & 1 & 0 & 0 & 1 & \ln x_4 \\
1 & 0 & 1 & -1 & -1 & \ln x_1 \\
1 & 0 & 1 & -1 & -1 & \ln x_2 \\
1 & 0 & 1 & -1 & -1 & \ln x_3 \\
1 & 0 & 1 & -1 & -1 & \ln x_4 \\
1 & -1 & -1 & 1 & 0 & \ln x_1 \\
1 & -1 & -1 & 1 & 0 & \ln x_2 \\
1 & -1 & -1 & 1 & 0 & \ln x_3 \\
1 & -1 & -1 & 1 & 0 & \ln x_4 \\
1 & -1 & -1 & 0 & 1 & \ln x_1 \\
1 & -1 & -1 & 0 & 1 & \ln x_2 \\
1 & -1 & -1 & 0 & 1 & \ln x_3 \\
1 & -1 & -1 & 0 & 1 & \ln x_4 \\
1 & -1 & -1 & -1 & -1 & \ln x_1 \\
1 & -1 & -1 & -1 & -1 & \ln x_2 \\
1 & -1 & -1 & -1 & -1 & \ln x_3 \\
1 & -1 & -1 & -1 & -1 & \ln x_4
\end{pmatrix} \cdot \begin{pmatrix}
\ln \lambda \\
\beta_{A_1} \\
\beta_{A_2} \\
\beta_{B_1} \\
\beta_{B_2} \\
\alpha
\end{pmatrix}
\]

\[\Rightarrow \ln(-\ln S(x)) = X_1 \cdot \begin{pmatrix}
\ln \lambda \\
\beta_{A_1} \\
\beta_{A_2} \\
\beta_{B_1} \\
\beta_{B_2} \\
\alpha
\end{pmatrix}\]
This model is a linear model in the parameters $\ln \lambda$, $\beta_{A_1}$, $\beta_{A_2}$, $\beta_{B_1}$, $\beta_{B_2}$ and $\alpha$.

By proceeding in a similar way as in section 4.7.6, the estimated parameters of the Weibull distributions for the nine combinations of risk factor $A$ levels and risk factor $B$ levels can be solved from

$$
\begin{pmatrix}
\ln \hat{\lambda} \\
\hat{\beta}_{A_1} \\
\hat{\beta}_{A_2} \\
\hat{\beta}_{B_1} \\
\hat{\beta}_{B_2} \\
\hat{\alpha}
\end{pmatrix} = (X_1'X_1)^{-1}X_1' \cdot \ln \left\{ \frac{S \cdot \hat{\pi}_c}{1 - S \cdot \hat{\pi}_c} \right\}
$$

(4.7.38)

with $\hat{\pi}_c = p - (G_{\pi}V)'(G_{\pi}VG_{\pi})^{-1}C \cdot \ln \left\{ \frac{S \cdot p}{1 - S \cdot p} \right\}$ where $S$, $V$ and $p$ are defined in section 4.7.10.

Note that $\hat{\beta}_{A_3} = -(\hat{\beta}_{A_1} + \hat{\beta}_{A_2})$ and $\hat{\beta}_{B_3} = -(\hat{\beta}_{B_1} + \hat{\beta}_{B_2})$.

The estimated lambda parameters of the nine Weibull distributions for the nine combinations of risk factor $A$ levels and risk factor $B$ levels then are

$$
\begin{align*}
\hat{\lambda}_{A_1B_1} &= \exp(\ln \hat{\lambda} + \hat{\beta}_{A_1} + \hat{\beta}_{B_1}) \\
\hat{\lambda}_{A_1B_2} &= \exp(\ln \hat{\lambda} + \hat{\beta}_{A_1} + \hat{\beta}_{B_2}) \\
\hat{\lambda}_{A_1B_3} &= \exp(\ln \hat{\lambda} + \hat{\beta}_{A_1} + \hat{\beta}_{B_3}) \\
\hat{\lambda}_{A_2B_1} &= \exp(\ln \hat{\lambda} + \hat{\beta}_{A_2} + \hat{\beta}_{B_1}) \\
\hat{\lambda}_{A_2B_2} &= \exp(\ln \hat{\lambda} + \hat{\beta}_{A_2} + \hat{\beta}_{B_2}) \\
\hat{\lambda}_{A_2B_3} &= \exp(\ln \hat{\lambda} + \hat{\beta}_{A_2} + \hat{\beta}_{B_3}) \\
\hat{\lambda}_{A_3B_1} &= \exp(\ln \hat{\lambda} + \hat{\beta}_{A_3} + \hat{\beta}_{B_1}) \\
\hat{\lambda}_{A_3B_2} &= \exp(\ln \hat{\lambda} + \hat{\beta}_{A_3} + \hat{\beta}_{B_2}) \\
\hat{\lambda}_{A_3B_3} &= \exp(\ln \hat{\lambda} + \hat{\beta}_{A_3} + \hat{\beta}_{B_3})
\end{align*}
$$

The estimated lambda parameter of the baseline Weibull distribution then is

$$
\hat{\lambda}_0 = \exp(\ln \hat{\lambda})
$$
so that

\[
\begin{align*}
\tilde{\lambda}_{A_1B_1} &= \tilde{\lambda}_0 \times index_{A_1} \times index_{B_1} \\
\tilde{\lambda}_{A_1B_2} &= \tilde{\lambda}_0 \times index_{A_1} \times index_{B_2} \\
\tilde{\lambda}_{A_1B_3} &= \tilde{\lambda}_0 \times index_{A_1} \times index_{B_3} \\
\tilde{\lambda}_{A_2B_1} &= \tilde{\lambda}_0 \times index_{A_2} \times index_{B_1} \\
\tilde{\lambda}_{A_2B_2} &= \tilde{\lambda}_0 \times index_{A_2} \times index_{B_2} \\
\tilde{\lambda}_{A_2B_3} &= \tilde{\lambda}_0 \times index_{A_2} \times index_{B_3} \\
\tilde{\lambda}_{A_3B_1} &= \tilde{\lambda}_0 \times index_{A_3} \times index_{B_1} \\
\tilde{\lambda}_{A_3B_2} &= \tilde{\lambda}_0 \times index_{A_3} \times index_{B_2} \\
\tilde{\lambda}_{A_3B_3} &= \tilde{\lambda}_0 \times index_{A_3} \times index_{B_3}.
\end{align*}
\]

These ten Weibull distributions all have the same estimated alpha parameter \( \tilde{\alpha} \).

The SAS/IML program to fit a Weibull regression model with two categorical risk factors (constant shape parameter) to grouped survival data with staggered entry of policies appears in Appendix A.

Generalization to a regression model with more than two risk factors is obvious.
Chapter 5

APPLICATION TO DATA FROM THE INSURANCE INDUSTRY

5.1 Description of the Data Set

5.1.1 Introduction

An extensive data set from an insurance company, containing information on policies written over the last few years, is available and permission has been given by this company to use this data set to illustrate the theoretical principles developed in the previous two chapters.

5.1.2 The raw data set of policies

A subgroup of policies is formed by selecting only mortgage protection policies written during four selected months, namely March 1998, June 1998, November 1998 and March 1999. This subgroup or smaller data set consists of the lifetimes of 10077 policies, together with some concomitant information on other variables such as age of the policyholder, credit turnover of his bankaccount and a score value, determined by the company.

Consider the following experimental design as illustrated in Figure 5.1. The 10077 policies enter the study at four different times (staggered entry). The event to be occurred is a lapse. The lifetime of a policy is measured from inception date up to the lapsing date. If the lapsing date is prior to the pre-determined cut-off date of 15 April 2001, then the
lifetime is **observed** (an uncensored observation). If a policy is still in force (alive) when the termination point is reached, the lifetime of this policy is **right-censored**.

From the 2586 policies with entry date March 1998 (inception dates between 1 March 1998 and 31 March 1998), a total of 1666 policies have lifetimes 37 months and more and thus were right-censored. From the 2809 policies with entry date June 1998 (inception dates between 1 June 1998 and 30 June 1998), a total of 1924 policies have lifetimes 34 months and more and were censored. From the 2286 policies with entry date November 1998 (inception dates between 1 November 1998 and 30 November 1998), a total of 1674 policies have lifetimes 28 months and more and were censored. From the 2396 policies with entry date March 1999 (inception dates between 1 March 1999 and 31 March 1999), a total of 1848 policies have lifetimes 24 months and more and were censored.
Figure 5.1: **Experimental design for illustrative data set**

- **Entry dates**: Mar98, Nov98, Jun98, Mar99
- **Cut off date**: 15 April 2001
- **Status**: a lapse
  - Observed lifetime of 20 months
- **Status**: in force
  - Censored lifetime of 28 months
5.1.3 The grouped data set of policies

The lifetimes of the policies that enter the study at March 1998 (called the first sample of size 2586) can be grouped into seven adjacent, non-overlapping fixed intervals

\[ [0; 12), [12; 17), [17; 24), [24; 28), [28; 34), [34; 37) \quad \text{and} \quad [37; \infty). \]

The lifetimes of the policies that enter the study at June 1998 (called the second sample of size 2809) can be grouped into six adjacent, non-overlapping fixed intervals

\[ [0; 12), [12; 17), [17; 24), [24; 28), [28; 34) \quad \text{and} \quad [34; \infty). \]

The lifetimes of the policies that enter the study at November 1998 (called the third sample of size 2286) can be grouped into five adjacent, non-overlapping fixed intervals

\[ [0; 12), [12; 17), [17; 24), [24; 28) \quad \text{and} \quad [28; \infty). \]

The lifetimes of the policies that enter the study at March 1999 (called the fourth sample of size 2396) can be grouped into four adjacent, non-overlapping fixed intervals

\[ [0; 12), [12; 17), [17; 24) \quad \text{and} \quad [24; \infty). \]

The four samples are assumed to be independent samples from multinomial populations. Four frequency distributions are formed when the observed and censored lifetimes of all the policies are grouped into the different class intervals and are shown in Table 5.1.

Figure 5.2: Histograms of the four relative frequency distributions
### 5.2 Fitting of a Lifetime Distribution

#### 5.2.1 A fixed censoring time

Consider the June 1998 group of policies as an example of a data set with a pre-assigned fixed censoring time at 15 April 2001. All these 2809 policies start at the same time. The censored lifetimes are grouped into the open interval $[34; \infty)$, while the observed lifetimes are grouped into intervals $[0; 12), [12; 17), [17; 24), [24; 28)$, and $[28; 34)$. Note that $x = (12, 17, 24, 28, 34)'$ is a $5 \times 1$ vector of upper class boundaries, $f = (118, 166, 229, 200, 172, 1924)'$ is a $6 \times 1$ vector of frequencies and $p = (0.0420078, 0.0590958, 0.0815237, 0.0711997, 0.0612318, 0.6849143)'$ is a $6 \times 1$ vector of relative frequencies. This vector is used as starting value for the iterative process.

One survival model is fitted to this grouped data set under constraints imposed by the Weibull/log-logistic/lognormal distribution. The double iterative procedure, as described in section 3.3.2 of chapter three, is illustrated by the following computer output when a Weibull model is fitted to the grouped data.

Figure 5.3 shows the histogram of the relative frequency distribution and the fitted survival distributions. It is clear that the lognormal and log-logistic models fit very well.
5.2.2 Staggered entry

Introduction

Consider Figure 5.2, the four histograms of the relative frequency distributions. Maximum likelihood estimates are to be found in the following ways.

1. One survival model is fitted to the four histograms under constraints imposed by the Weibull/log-logistic/lognormal distribution.

2. Four survival models (Weibull/log-logistic/lognormal models), one for each entry time, are fitted under constraints imposed by the Weibull/log-logistic/lognormal distribution and under further constraints that
   - \( \lambda_i \)'s are equal and \( \alpha_i \)'s are equal when fitting a Weibull or log-logistic
   - \( \mu_i \)'s are equal and \( \sigma_i \)'s are equal when fitting a lognormal.

3. A joint histogram is fitted to the four histograms of the four relative frequency distributions under constraints imposed by the experimental design.

The constraints imposed by the experimental design

Consider Figure 5.4, illustrating the constraints imposed by the experimental design.

\[
\begin{align*}
\pi_{1,j} &= \pi_{2,j} = \pi_{3,j} = \pi_{4,j} & j &= 1, 2, ..., 3 \\
\pi_{1,7} + \pi_{1,6} + \pi_{1,5} + \pi_{1,4} &= \pi_{2,6} + \pi_{2,5} + \pi_{2,4} \\
&= \pi_{3,5} + \pi_{3,4} \\
&= \pi_{4,4} \\
\pi_{1,5} &= \pi_{2,5} \\
\pi_{1,4} &= \pi_{2,4}
\end{align*}
\]

where \( \pi_{i,j} \) = probability of an observation from sample \( i \) will fall in the \( j^{th} \) interval

= interval probability of \( j^{th} \) interval from sample \( i \)  \( i = 1, 2, 3, 4 \quad j = 1, 2, ..., 7 \)
Figure 5.4: Constraints imposed by the experimental design
Fitting of one survival model to the four histograms

One survival model is fitted to the four histograms under constraints imposed by the Weibull/log-logistic/lognormal distribution. The estimated parameters and the Wald test with the discrepancy values are reported in Table 5.3.

<table>
<thead>
<tr>
<th>Survival model</th>
<th>Weibull</th>
<th>Log-logistic</th>
<th>Lognormal</th>
</tr>
</thead>
<tbody>
<tr>
<td>Maximum likelihood</td>
<td>In $\hat{\lambda}=-7.39252$</td>
<td>In $\hat{\lambda}=-7.959399$</td>
<td>$\hat{\mu}=3.8727296$</td>
</tr>
<tr>
<td>estimates</td>
<td>$\hat{\alpha}=1.8434286$</td>

</tbody>
</table>

The invariance property of the maximum likelihood estimator provides that the MLE of $\ln \hat{\lambda}$ can be written as $\ln \hat{\lambda}$.

Fitting of four survival models

Four survival models are fitted, one for each entry time, under constraints imposed by the Weibull/log-logistic/lognormal distribution and under further constraints that the parameters are equal.

The estimated parameters and the Wald test with the discrepancy values are reported in Table 5.4.

A joint histogram to the four histograms is needed to make a graphical representation of the fitted models.

**Fitting of a joint histogram to the four histograms**

A joint histogram is fitted to the four histograms under constraints imposed by the experimental design. Table 5.5 gives the fitted joint relative frequencies to the four sets of relative frequencies of the samples. A graphical representation of the joint histogram over the four histograms appears in Figure 5.5.

Figure 5.6 shows the fitted joint histogram and the fitted survival distributions. The log-normal and log-logistic models again fit the data very well.

Figure 5.5: Joint histogram over the four histograms
Fitted Distributions - Staggered Entry

Figure 5.6: Joint histogram and fitted survival distributions
Estimated survivor and hazard functions and percentiles

Once the parameters of the Weibull and log-logistic survival distributions have been estimated, estimated hazard rates and survivor functions and the odds of a lapse can be calculated for time $t$. Percentiles of these survival distributions can also be estimated.

The formulae and examples of calculations of the estimated hazard rates, survivor functions, odds of a lapse and percentiles of the Weibull and log-logistic survival distributions are given on the next page.

The survival curves and the graphs of the hazard rates of the fitted Weibull and log-logistic models are shown respectively in Figure 5.7 and Figure 5.8. From Figure 5.7 is it clear that the two survivor functions are equal for $t$—values up to 40 months, and then the probability for a policy to survive longer than time $t$ with $t > 40$ becomes larger for the log-logistic fitting than for the Weibull fitting. Note in Figure 5.8 the increasing trend of the Weibull hazard rates as $t$ increases.
WEIBULL

Estimated hazard function
\[ \hat{h}(t) = \lambda \cdot \hat{\alpha} \cdot t^{\hat{\alpha} - 1} \]
\[ \hat{h}(t) = e^{-7.39252 \cdot 1.8434286 \cdot t^{1.8434286 - 1}} \]
\[ \hat{h}(12) = 0.0092233 \]
\[ \hat{h}(24) = 0.0065055 \]

Estimated survivor function
\[ \hat{S}(t) = \exp(-\lambda \cdot t^{\hat{\alpha}}) \]
\[ \hat{S}(t) = \exp(-e^{-7.39252 \cdot 1.8434286}) \]
\[ \hat{S}(12) = 0.9416719 \]
\[ \hat{S}(24) = 0.806001 \]

Estimated odds of a lapse
\[ \hat{\text{odds}}(t) = \frac{1 - \hat{S}(t)}{\hat{S}(t)} = \exp(\hat{\lambda} \cdot t^{\hat{\alpha} - 1}) \]
\[ \hat{\text{odds}}(t) = \frac{1 - \hat{S}(t)}{\hat{S}(t)} = \exp(e^{-7.39252 \cdot 1.8434286 - 1}) \]
\[ \hat{\text{odds}}(12) = 0.061941 \]
\[ \hat{\text{odds}}(24) = 0.240693 \]

Estimated percentiles
\[ \hat{t}_p = \left( \frac{\alpha}{\lambda} \cdot \ln \frac{100}{100 - p} \right) \]
\[ \hat{t}_{50} = \left( \frac{1}{e^{-7.39252 \cdot \ln \frac{100}{100 - 50}}} \right) \]
\[ \hat{t}_{50} = 45.21 \]

LOG-LOGISTIC

Estimated hazard function
\[ \hat{h}(t) = \frac{\lambda \cdot \hat{\alpha} \cdot t^{\hat{\alpha} - 1}}{(1 + \lambda \cdot t^{\hat{\alpha})}} \]
\[ \hat{h}(t) = \frac{e^{-7.959399 \cdot 2.0647366 \cdot t^{2.0647366 - 1}}}{(1 + e^{-7.959399 \cdot t^{2.0647366}})} \]
\[ \hat{h}(12) = 0.0095996 \]
\[ \hat{h}(24) = 0.0170517 \]

Estimated survivor function
\[ \hat{S}(t) = \frac{1}{1 + \lambda \cdot t^{\hat{\alpha}} \}
\[ \hat{S}(t) = \frac{1}{1 + e^{-7.959399 \cdot t^{2.0647366}} \]
\[ \hat{S}(12) = 0.9442083 \]
\[ \hat{S}(24) = 0.8017956 \]

Estimated odds of a lapse
\[ \hat{\text{odds}}(t) = \frac{1 - \hat{S}(t)}{\hat{S}(t)} = \hat{\lambda} \cdot t^{\hat{\alpha}} \]
\[ \hat{\text{odds}}(t) = \frac{1 - \hat{S}(t)}{\hat{S}(t)} = e^{-7.959399 \cdot t^{2.0647366}} \]
\[ \hat{\text{odds}}(12) = 0.0590884 \]
\[ \hat{\text{odds}}(24) = 0.2472006 \]

Estimated percentiles
\[ \hat{t}_p = \left( \frac{\alpha}{\lambda} \cdot \frac{p}{100 - p} \right) \]
\[ \hat{t}_{50} = \left( \frac{1}{e^{-7.959399 \cdot \frac{50}{100 - 50}}} \right) \]
\[ \hat{t}_{50} = 47.22 \]

</table>

At the Weibull model, the median time to a lapse of a policy is estimated as 45.21 months and the odds of a lapse at 45.21 months is 1, that means $P(T > 45.21 \text{ months}) = P(T < 45.21 \text{ months})$. At the log-logistic model, the median time to a lapse of a policy is estimated as 47.22 months and the odds of a lapse at 47.22 months is 1, that means $P(T > 47.22 \text{ months}) = P(T < 47.22 \text{ months})$.

It is evident from the estimates of the percentile lifetimes that 20% of the policies will not lapse within 71 months under a Weibull model (see Weibull’s P80), while 30% of the policies will not lapse within 71 months under a log-logistic model (see log-logistic’s P70).

Note again the equal percentile estimates for the two distributions up to 40 months, confirming the pattern that was detected in the survival curves in Figure 5.7.
5.3 Fitting of Parametric Regression Models

5.3.1 Introduction

A survival model is fitted for each level of a risk factor or combination of levels of risk factors by using maximum likelihood estimation of parameters subject to constraints.

The fitting of regression models is illustrated where the effect of the risk factors (covariates) is to alter the scale parameter $\lambda$, while the shape parameter $\alpha$ remains constant. Applications are also done where both parameters alter.

The fitting of log-logistic regression models and Weibull regression models will be discussed only for staggered entry of policies.

5.3.2 A survival model for each level of a risk factor

Consider one risk factor AGE on three levels [18;35), [35;45) and [45+) years. The 10077 observations are distributed in the three age groups as follows: 3644 in age group [18;35), 3425 in age group [35;45) and 3008 in age group [45+). A regression model is fitted to the grouped survival data where each policy has information on the entry period as well as the age level. The grouped lifetimes of the policies with staggered entry as well as the concomitant information on AGE are given in Table 5.7.

The combined frequency vector $f$ is defined as

$$
    f' = (f'_{11}, f'_{12}, f'_{13}, f'_{21}, f'_{22}, f'_{23}, f'_{31}, f'_{32}, f'_{33}, f'_{43})
$$

$f'_{il}$ is the frequency vector for the $i^{th}$ entry group and the $l^{th}$ AGE level, $i = 1, 2, 3, 4$ and $l = 1, 2, 3$.

$$
    f_{11} = (29, 59, 95, 73, 108, 15, 642)'
$$

$$
    f_{12} = (21, 50, 91, 45, 75, 13, 553)'
$$

$$
    f_{13} = (16, 49, 68, 39, 67, 7, 471)'
$$

$$
    f_{21} = (41, 75, 103, 92, 83, 628)'
$$

$$
    f_{22} = (49, 62, 61, 66, 54, 753)'
$$

\[ f_{42} = (54, 61, 68, 616)' \]

\[ f_{43} = (50, 45, 70, 659)' \]

The vectors \( x_i \) \( i = 1, 2, 3, 4 \) of upper class boundaries for the \( i^{th} \) entry group are

\[
\begin{align*}
{x_1} = & \begin{pmatrix} 12 \\ 17 \\ 24 \\ 28 \\ 34 \\ 37 \end{pmatrix} & {x_2} = & \begin{pmatrix} 12 \\ 17 \\ 24 \\ 28 \\ 34 \end{pmatrix} & {x_3} = & \begin{pmatrix} 12 \\ 17 \\ 24 \\ 28 \end{pmatrix} & {x_4} = & \begin{pmatrix} 12 \\ 17 \end{pmatrix} .
\end{align*}
\]

From the estimated regression parameters, survival model parameters can be found for each level of this risk factor as well as for the baseline distribution.
The shape parameter remains constant

The estimated regression coefficients of the regression model where the effect of the risk factor AGE is to alter the scale parameter $\lambda$, while the shape parameter $\alpha$ remains constant, are reported in Table 5.8.

Table 5.8: Fitting a regression model (constant shape) to grouped data with one risk factor

<table>
<thead>
<tr>
<th>Effect</th>
<th>Maximum likelihood estimates</th>
<th>Regression model</th>
</tr>
</thead>
<tbody>
<tr>
<td>Baseline mean</td>
<td>$\ln \lambda_0 = \ln \hat{\lambda}_0$</td>
<td>Log-logistic: 7.981750, 0.180958</td>
</tr>
<tr>
<td>Age [18;35]</td>
<td>$\hat{\beta}_{A_1}$</td>
<td></td>

</tr>
</tbody>
</table>

The estimated lambda parameters of the three survival distributions for the three AGE levels then are

$$\hat{\lambda}_{A_1} = \exp(\ln \hat{\lambda}_0 + \hat{\beta}_{A_1})$$
$$\hat{\lambda}_{A_2} = \exp(\ln \hat{\lambda}_0 + \hat{\beta}_{A_2})$$
$$\hat{\lambda}_{A_3} = \exp(\ln \hat{\lambda}_0 + \hat{\beta}_{A_3})$$

with the same estimated alpha parameter $\hat{\alpha}$. These parameters are summarized for each AGE level in Table 5.9.

Table 5.9: Parameters of a survival model (constant shape) for each level of risk factor AGE

</tr>
</tbody>
</table>
The shape parameter alters

The fitting of regression models is illustrated where the effect of the risk factors (covariates) is to alter both the scale parameter \( \lambda \) and the shape parameter \( \alpha \). The estimated regression coefficients of this regression model are reported in Table 5.10.

Table 5.10: Fitting a regression model (shape alters) to grouped data with one risk factor

<table>
<thead>
<tr>
<th>Effect</th>
<th>Maximum likelihood estimates</th>
<th>Regression model</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>

</tr>
<tr>
<td></td>
<td>( \hat{\alpha}_{A_3} )</td>
<td>0.039035</td>
</tr>
</tbody>
</table>

The weighted mean of the \( \hat{\alpha}_{A_i} \)'s \( i = 1, 2, 3 \) is used as an estimate for the shape parameter of the baseline distribution.

The estimated lambda parameters of the three survival distributions for the three AGE levels are calculated from Table 5.10 as

\[
\hat{\lambda}_{A_1} = \exp(\ln \hat{\lambda}_0 + \hat{\beta}_{A_1}) \\
\hat{\lambda}_{A_2} = \exp(\ln \hat{\lambda}_0 + \hat{\beta}_{A_2}) \\
\hat{\lambda}_{A_3} = \exp(\ln \hat{\lambda}_0 + \hat{\beta}_{A_3})
\]

Each age group survival distribution has its own estimated alpha parameter.

These parameters for each AGE level are summarized in Table 5.11, together with the Wald test and discrepancy value to compare the fitted survival distributions at each AGE level.

A joint histogram to the data of each AGE level **over the four entry groups** is needed to make a graphical representation of the fitted models for each AGE level. Table 5.12 gives the three sets of fitted joint frequencies for the three AGE levels. This fitting was done by maximum likelihood estimation subject to constraints imposed by the experimental design. The Wald test and discrepancy value measure the goodness-of-fit.

Figure 5.9 shows the fitted joint histogram and the fitted survival distributions for age group [18;35).

Figure 5.10 shows the fitted joint histogram and the fitted survival distributions for age group [35;45).

Figure 5.11 shows the fitted joint histogram and the fitted survival distributions for age group [45+).

In all the cases the survival models fit very well, with the log-logistic model slightly better than the Weibull model, as indicated by the discrepancy values in Table 5.11.
Figure 5.9: Joint histogram and fitted survival distributions for age group [18;35]

5.3.3 Deriving of indices and risk scores from log-logistic regression model

Once the parameters of the log-logistic baseline distribution and log-logistic age group distributions have been estimated, estimated hazard and survivor functions, odds of a lapse, odds ratios and hazard ratios at time \( t \) can be calculated.

The odds ratio for age group \([18;35]\) is the relative odds of a lapse at time \( t \) of a policy, with the age of the policyholder in \([18;35]\), compared to a policy with the baseline characteristics. The odds ratios for the three age groups result in a set of indices, showing the effect of each age group on the baseline odds of a lapse at time \( t \).

The hazard ratio for age group \([18;35]\) is the relative hazard rate of a lapse at time \( t \) of a policy, with the age of the policyholder in \([18;35]\), compared to a policy with the baseline characteristics. The hazard ratios for the three age groups result in a set of risk scores, showing the effect of each age group on the baseline hazard rate of a lapse at time \( t \).

Percentiles of the four log-logistic survival distributions can also be estimated.

The calculations of estimated hazard and survivor functions, odds of a lapse, odds ratios and hazard ratios are illustrated on the following five pages.

The survival curves and the graphs of the hazard rates of the fitted log-logistic age group models are shown in Figure 5.12 and Figure 5.13 with measure of comparison the baseline curves. These survival curves can be described as graphs of the covariate-adjusted survivor functions, and the other graphs as graphs of the covariate-adjusted hazard rates.

The effects of the agegroups on the baseline distribution are clearly depicted in these figures. It is evident from these two figures that the policyholders in the age group 45+ have the lowest risk for their policies to lapse. Note the the survival curve of this age group lies above the baseline survival curve in Figure 5.12, while the curve of the hazard rates for this age group lies the furthest distance beneath the baseline curve of hazard rates. Similarly age group \([18;35]\) has the highest risk for their policies to lapse.
Estimated Hazard Function at log-logistic regression model

Figure 5.12: Survival curves of fitted log-logistic age group models
HAZARD RATES OF LOG-LOGISTIC AGE GROUPS

Figure 5.13: Graphs of hazard rates of fitted log-logistic age group models
For a constant shape parameter in the log-logistic distributions, the indices (estimated odds ratios) may be obtained also from the exponent of the $\hat{\beta}$-values in the log-logistic regression model, for example

$$e^{\hat{\beta}_1} = e^{0.160058} = 1.198365$$

$$e^{\hat{\beta}_2} = e^{-0.034975} = 0.965629$$

$$e^{\hat{\beta}_3} = e^{-0.145983} = 0.864172.$$ 

The indices of the three age groups, estimated from the log-logistic regression model, are compared to the indices, obtained from the logit model, in Table 5.13.

Table 5.13: Comparison of indices: log-logistic regression model and logit model

The index of age group [18;35] of 1.198365 shows the effect of this age group on the baseline odds of a lapse. This effect is multiplicative on the baseline odds of a lapse. Thus the effect of age group [18;35] is to increase the baseline odds of a lapse by a factor 1.198365.

From Table 5.13 follows that one log-logistic regression model provides indices for any time value, while a new logit model has to be built for a fixed time value, say t=12 months, conditional on a restricted experimental design where all the policies must have an exposure of at least one year when investigating the lapses of policies in the first year. There is no such restrictions in the more general experimental design for the log-logistic regression model where all the policies can be used in the analysis, even those policies with inception dates very close to the cut-off point.

Predicted indices from the log-logistic regression model, for varying time values, are shown in Table 5.14 (constant shape) and in Table 5.15 (shape alters).

Predicted risk scores from the log-logistic regression model, for varying time values, are shown in Table 5.16 (constant shape) and in Table 5.17 (shape alters).

For a **constant shape parameter** in the log-logistic distributions, the $p^{th}$ percentile of the baseline lifetime distribution can be calculated from

$$\left(\frac{1}{\lambda_0} \cdot \frac{p}{100 - p}\right)^{\frac{1}{\alpha}}$$

and that of the age group distributions from

$$\left(\frac{1}{\lambda_{Ai}} \cdot \frac{p}{100 - p}\right)^{\frac{1}{\alpha}} \quad i = 1, 2, 3.$$ 

Note that the latter is equal to the $p^{th}$ percentile of the baseline distribution multiplied by the specific index to the power $\frac{1}{\alpha}$.

For a **shape parameter that alters**, the formulas change to

$$\left(\frac{1}{\lambda_0} \cdot \frac{p}{100 - p}\right)^{\frac{1}{\alpha_0}} \quad \text{and} \quad \left(\frac{1}{\lambda_{Ai}} \cdot \frac{p}{100 - p}\right)^{\frac{1}{\alpha_{Ai}}} \quad i = 1, 2, 3.$$ 

The estimated percentiles of the baseline and the age group log-logistic distributions for a constant shape parameter as well as for different shape parameters are reported in Table 5.18.

</table>

The median time to a lapse of a policy, over all three age groups, is 47.59 months. The baseline odds of a lapse at 47.59 months is 1, that means that $P(T > 47.59 \text{ months}) = P(T < 47.59 \text{ months})$. 
5.3.4 Deriving of indices and risk scores from Weibull regression model

Once the parameters of the Weibull baseline distribution and Weibull age group distributions have been estimated, estimated hazard and survivor functions, odds of a lapse, odds ratios and hazard ratios at time \( t \) can be calculated.

The odds ratio for age group \([18;35]\) is the relative odds of a lapse at time \( t \) of a policy, with the age of the policyholder in \([18;35]\), compared to a policy with the baseline characteristics. The odds ratios for the three age groups result in a set of indices, showing the effect of each age group on the baseline odds of a lapse at time \( t \).

The hazard ratio for age group \([18;35]\) is the relative hazard rate of a lapse at time \( t \) of a policy, with the age of the policyholder in \([18;35]\), compared to a policy with the baseline characteristics. The hazard ratios for the three age groups result in a set of risk scores, showing the effect of each age group on the baseline hazard rate of a lapse at time \( t \).

Percentiles of the four Weibull survival distributions can also be estimated.

The calculations of estimated hazard and survivor functions, odds of a lapse, odds ratios and hazard ratios are illustrated on the following five pages.

The survival curves and the graphs of the hazard rates of the fitted Weibull age group models are shown in Figure 5.14 and Figure 5.15.

Hazard ratio of an age group is constant over time

Hazard ratio is called a risk score

One set of risk scores, irrespective of time

Hazard ratio of an age group depends on time

Hazard ratio is called a risk score

Two sets of risk scores, one for \(t=12\) and one for \(t=24\)
Figure 5.14: Survival curves of fitted Weibull age group models
Figure 5.15: Graphs of hazard rates of fitted Weibull age group models
For a constant shape parameter in the Weibull distributions, the risk scores (estimated hazard ratios) may be obtained also from the exponent of the $\hat{\beta}$-values in the Weibull regression model, for example

\[
\begin{align*}
\exp(\hat{\beta}_{A_1}) &= e^{0.1590898} &= 1.1724432 \\
\exp(\hat{\beta}_{A_2}) &= e^{-0.033957} &= 0.966133 \\
\exp(\hat{\beta}_{A_3}) &= e^{-0.125133} &= 0.8823795.
\end{align*}
\]

The indices (estimated odds ratios) of the three age groups, estimated from the Weibull regression model, are compared to the indices, obtained from the logit model, in Table 5.19.

The index of age group [45+] of 0.879283 shows the effect of this age group on the baseline odds of a lapse. This effect is multiplicative on the baseline odds of a lapse. Thus the effect of age group [45+] is to decrease the baseline odds of a lapse by a factor 0.879283.

</table>

From Table 5.19 follows that one Weibull regression model provides indices for any time value, while a new logit model has to be built for a fixed time value, say t=12 months, conditional on a restricted experimental design where all the policies must have an exposure of at least one year when investigating the lapses of policies in the first year. There is no such restrictions in the more general experimental design for the Weibull regression model where all the policies can be used in the analysis, even those policies with inception dates very close to the cut-off point.

Predicted indices from the Weibull regression model, for varying time values, are shown in Table 5.20 (constant shape) and in Table 5.21 (shape alters).

Predicted risk scores from the Weibull regression model, for varying time values, are shown in Table 5.22 (constant shape) and in Table 5.23 (shape alters).

</tbody>
</table>
For a constant shape parameter in the Weibull distributions, the \( p^{th} \) percentile of the baseline lifetime distribution can be calculated from

\[
\frac{1}{\lambda_0} \cdot \ln \left( \frac{100}{100 - p} \right) \cdot \frac{1}{\tilde{\alpha}}
\]

and that of the age group distributions from

\[
\frac{1}{\lambda_{A_i}} \cdot \ln \left( \frac{100}{100 - p} \right) \cdot \frac{1}{\tilde{\alpha}} \quad i = 1, 2, 3.
\]

Note that the latter is equal to the \( p^{th} \) percentile of the baseline distribution multiplied by the specific index to the power \(-\frac{1}{\tilde{\alpha}}\).

For a shape parameter that alters, the formulae change to

\[
\frac{1}{\lambda_0} \cdot \ln \left( \frac{100}{100 - p} \right) \cdot \frac{1}{\tilde{\alpha}_0} \quad \text{and} \quad \frac{1}{\lambda_{A_i}} \cdot \ln \left( \frac{100}{100 - p} \right) \cdot \frac{1}{\tilde{\alpha}_{A_i}} \quad i = 1, 2, 3.
\]

The estimated percentiles of the baseline and the age group Weibull distributions for a constant shape parameter as well as for different shape parameters are reported in Table 5.24.

5.3.5 The fitting of a regression model with a continuous predictor

Consider AGE as a continuous predictor that can be categorized into three age groups. The ordinal covariate $Z$ takes on the values

$z=1$ for the age group $[18;35)$

$z=2$ for the age group $[35;45)$

$z=3$ for age group $[45+).$

The midpoints of the age group intervals can also be used as values of the continuous predictor AGE, that means

$z = \frac{18+34}{2} = 26$ for age group $[18;35)$

$z = \frac{35+44}{2} = 39.5$ for age group $[35;45)$

$z = \frac{45+50}{2} = 52$ for age group $[45+)$

if 60 months is assumed to be an upper limit for the open interval.

A log-logistic as well as a Weibull regression model are fitted to the grouped survival data with known $z$-values. From the estimated regression parameters, survival model parameters can be found for each age group as well as for the baseline distribution.

The estimated regression coefficients of these two regression models are reported in Table 5.25.

Table 5.25: Fitting a regression model (constant shape) to grouped data with one continuous predictor

<table>
<thead>
<tr>
<th>Effect</th>
<th>Maximum likelihood estimates</th>
<th>Log-logistic $z$-values</th>
<th>Weibull $z$-values</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Maximum likelihood estimates</td>
<td>$z$-values</td>
<td>$z$-values</td>
</tr>
<tr>
<td>Baseline mean</td>
<td>$\ln \lambda_0 = \ln \hat{\lambda}_0$</td>
<td>1 2 3</td>

</tr>
<tr>
<td>Age</td>
<td>$\hat{\beta}$</td>
<td>-0.166957</td>
<td>-0.012856</td>
</tr>
</tbody>
</table>

The estimated lambda parameters of the three survival distributions for the three age groups
then are

\[
\begin{align*}
\hat{\lambda}_{\text{Age}1} &= \exp(\ln \hat{\lambda}_0 + \hat{\beta} \times 1) \\
\hat{\lambda}_{\text{Age}2} &= \exp(\ln \hat{\lambda}_0 + \hat{\beta} \times 2) \\
\hat{\lambda}_{\text{Age}3} &= \exp(\ln \hat{\lambda}_0 + \hat{\beta} \times 3)
\end{align*}
\]

or

\[
\begin{align*}
\hat{\lambda}_{\text{Age}1} &= \exp(\ln \hat{\lambda}_0 + \hat{\beta} \times 26) \\
\hat{\lambda}_{\text{Age}2} &= \exp(\ln \hat{\lambda}_0 + \hat{\beta} \times 39.5) \\
\hat{\lambda}_{\text{Age}3} &= \exp(\ln \hat{\lambda}_0 + \hat{\beta} \times 52)
\end{align*}
\]

with the same estimated alpha parameter \(\hat{\alpha}\). These parameters are summarized for each age group in Table 5.26.

5.3.6 A survival model for each combination of levels of two risk factors

Consider two risk factors AGE and SCORE where AGE has three levels [18;35), [35;45) and [45+) years and SCORE has three levels 'Low', 'Medium' and 'High'.

A cross tabulation of AGE and SCORE for the 10077 observations are given in Table 5.27.

<table>
<thead>

A joint histogram to the data of each combination of AGE and SCORE levels over the four entry groups is needed to make a graphical representation of the fitted models for each combination of AGE and SCORE levels. Table 5.31 gives the nine sets of fitted joint frequencies for the nine combinations of AGE and SCORE levels. This fitting was done by maximum likelihood estimation subject to constraints imposed by the experimental design. The Wald test and discrepancy value measure the goodness-of-fit.

5.3.7 Relationship between the indices of the regression and logit model

Once the parameters of the baseline survival distribution and the nine age-score distributions have been estimated, estimated hazard and survivor functions, odds of a lapse, odds ratios and hazard ratios at time \( t \) can be calculated in a similar way as at the regression model with one risk factor (constant shape).

The odds ratio for age group [35;45] and a medium score is the relative odds of a lapse at time \( t \) of a policy, where the age of the policyholder is in [35;45] years and the policyholder has a medium score, compared to a policy with the baseline characteristics.

As an example, the odds ratio for a lapse of a policy at time \( t \) is calculated if the age of the policyholder is in the age group [18;35] years and the policyholder has a low score.

\[
\hat{\text{odds ratio}}_{A_1B_1}(t) = \frac{\text{odds}_{A_1B_1}(t)}{\text{odds}_0(t)}
\]

where

\[
\text{odds}_{A_1B_1}(t) = \frac{1 - \hat{S}_{A_1B_1}(t)}{\hat{S}_{A_1B_1}(t)} = \hat{\lambda}_{A_1B_1} \cdot \hat{r}^\alpha
\]

\[\Rightarrow \text{odds}_{A_1B_1}(12) = e^{-7.297757} \cdot 12^{2.249510} = 0.181240\]

\[\Rightarrow \text{odds ratio}_{A_1B_1}(12) = \frac{0.181240}{0.051768} = 3.501004\]

This odds ratio of 3.5 is called an index and shows the effect of age group [18;35] and a low score on the baseline odds of a lapse at time \( t \). This effect is multiplicative on the baseline odds of a lapse. Thus the effect of the combination of this age group and this score group is to increase the baseline odds of a lapse by a factor 3.5.
The other eight indices for the log-logistic regression model can be calculated in a similar way.

The relationship between the indices of the nine age-score combinations, obtained from the log-logistic model, must be compared to the six 'indices', obtained from the loglinear logit model for the three age levels and the three score levels.

Recall that the loglinear logit model models

$$\ln(\text{odds of a lapse}) = \mu + \lambda_i^\text{AGE} + \lambda_j^\text{SCORE}$$

where

$$\mu = \text{the overall mean effect, over all AGE levels and SCORE levels}$$

$$\lambda_i^\text{AGE} = \text{effect of the } i^{th} \text{ level of AGE}$$

$$\lambda_j^\text{SCORE} = \text{effect of the } j^{th} \text{ level of SCORE}.$$ 

The odds of a lapse then can be modelled as

$$\text{odds of lapse} = e^{\mu + \lambda_i^\text{AGE} + \lambda_j^\text{SCORE}}$$

$$= e^\mu \cdot e^{\lambda_i^\text{AGE}} \cdot e^{\lambda_j^\text{SCORE}}$$

$$= \text{geometric mean odds} \cdot \text{index}_{\text{AGE}_i} \cdot \text{index}_{\text{SCORE}_j}$$

$$i=1,2,3 \text{ and } j=1,2,3.$$ 

The six 'indices' obtained from the logit model for each age level and for each score level are given in Table 5.32.

**Table 5.32: Logit model indices for three age levels and three score levels obtained from the logit model**

<table>

<td>2817</td>
<td>0.7678</td>
<td>0.7418</td>
<td></td>
</tr>
</tbody>
</table>

The odds of a lapse of a policy in the first year, with the policyholder in the age group [18;35) and a low score, is calculated from the logit model as the product of the baseline
odds and the index of age group \((18;35)\) of 1.1558 and the index of score group 'Low' of 2.2622 for the first year \((t=12)\), this means

\[
\text{odds}_{A_1B_1}(12) = 0.0537 \times 1.1558 \times 2.2622 = 0.1404
\]

\[
\Rightarrow P(\text{lapse of this policy}) = \frac{\text{odds}}{1 + \text{odds}} = \frac{0.1404}{1.1404} = 0.1231
\]

Thus the odds ratio (relative odds of a lapse of this policy) is calculated by

\[
\text{oddsratio}_{A_1B_1}(12) = \frac{\text{odds}_{A_1B_1}(12)}{\text{baseline odds}} = \frac{0.1404}{0.0537} = 2.614525
\]

It is clear that this odds ratio can easily be found by multiplication of the two indices from the logit model, that is

\[
\text{oddsratio}_{A_1B_1}(12) = \text{index}_{A_1}(12) \times \text{index}_{B_1}(12) = 1.1558 \times 2.2622 = 2.614651
\]

The odds ratio shows the effect of the combination of this age group and this score group on the baseline odds of a lapse. This effect is multiplicative on the baseline odds of a lapse. Thus the effect of the combination of this age group and this score group is to increase the baseline odds of a lapse by a factor 2.614.

In the context of survival analysis, this odds ratio can be called an index for age group \((18;35)\) and a low score. The odds ratios for the nine age-score combinations result in a set of indices, showing the effect of each combination of age group and score on the baseline odds of a lapse at time \(t\).

The odds ratios (indices) of the nine age-score groups, estimated from the log-logistic or Weibull regression model, are compared to the odds ratios, obtained from the logit model, in Table 5.33.

<td>0.7 0.6</td>
</tr>
</tbody>
</table>
It is clear from Table 5.33 that the odds ratios are constant over time at the log-logistic regression model, but the odds ratios do not remain constant over time at the Weibull regression model.

From Table 5.33 follows that one log-logistic regression model provides odds ratios (indices) for any time value, while a new logit model has to be built for a fixed time value, say t = 12 months, conditional on a restricted experimental design where all the policies must have an exposure of at least one year when investigating the lapses of policies in the first year. There is no such restrictions in the more general experimental design for the log-logistic regression model where all the policies can be used in the analysis, even those policies with inception dates very close to the cut-off point.

The same argument holds for the Weibull regression model, except that the odds ratios do not remain constant over time.

### 5.3.8 Median lifetimes of the nine survival distributions

The median lifetimes (in months) of the nine survival distributions can also be estimated and compared with the baseline median. The medians are reported in Table 5.34. It is evident from Table 5.34 that the log-logistic and Weibull models deliver the same results. The estimated median values of the nine combinations of age and score levels suggest that the policy of a policyholder with a low score, coming from any age group, has a high risk to lapse. The policy of a policyholder in age group 45+ with a medium score has the lowest risk to lapse, lower than the combination 45+ and a high score.

Chapter 6

RESUMÉ

This thesis focuses on the analysis of insurance policy lifetimes in the form of grouped data, where the lifetime of a policy is measured from the inception date (entry month) up to the lapsing date (month in which policy lapsed) or a pre-determined cut-off date. Data from the insurance industry are extensive data sets with very large sample sizes. The focus in this thesis is on the estimation of lifetime distributions, based on a large sample of discrete lifetimes of policies that are grouped into intervals of lifetimes. The aim of the research is the statistical modelling of parametric survival distributions of grouped survival data of long- and short-term policies in the insurance industry, by means of a method of maximum likelihood estimation subject to constraints. This scenario has become extremely important, not only for application in the actuarial context, but also in other fields.

In this thesis, the analysis takes account of the actual lifetime (duration) of the policy rather than just recording the fact that the policy lapsed or was still alive after (say) twelve months. In other words, the response variable, lifetime, is a continuous one, and the whole distribution of lifetimes can be used. A general experimental design admits that all the policies can be used in the analysis, even those policies with inception dates very close to the cut-off point.

Special attention has been given to staggered entry of policies, where policies written in different months or time-periods have different entry times.

The methodology of maximum likelihood estimation subject to constraints, used in this thesis, leads to explicit expressions for the estimates of the parameters, as well as for
approximated variances and covariances of the estimates, which gives exact maximum likelihood estimates of the parameters. This makes direct extension to more complex designs feasible.

Once the parameters of the survival distributions have been estimated, estimated hazard and survivor functions, odds of a lapse, odds ratios and hazard ratios at time $t$ can be directly calculated, as well as estimated percentiles for the fitted survival distributions. These estimates form the statistical foundation for scientific decisionmaking with respect to actuarial design, maintenance and marketing of insurance policies.

**Parametric regression models** are fitted and important indicators of the effect of the covariates are defined such as risk scores (hazard ratios) and indices (odds ratios). This is in contrast to the famous semiparametric Cox's proportional hazards model. David Oakes states in the chapter on Survival Analysis in [39] that "following the incorporation of software for fitting proportional hazards models into packages such as BMDP and SAS, this model of Cox, for better or worse, became standard for the analysis of survival data. But the assumption of proportional hazards has no compelling mathematical justification and is often found to be false in applications."

It is generally assumed in the actuarial industry that incorrect assumptions regarding lifetime distributions have severe implications with respect to lapse probabilities and estimated income. For this reason non-parametric and semi-parametric models are standard practice. The implications of a proper and sound parametric model are far-reaching for the characterization of lapse probabilities and income, which are the corner stones of the insurance industry. It directly determines lapse indices in terms of risk factors, including the period of lapsing under consideration. It also determines the behaviour of such indices over time. It can also be assumed that the use of grouped data for determining lifetime distributions is more robust with respect to wrong assumptions than continuous data.

In this way a contribution is made to the global handling of lapse indices and risk scores. For example, if a log-logistic distribution holds, the indices are constant, independent of the lapsing period. If a Weibull distribution holds, the risk scores are constant, independent of the lapsing period. In any event, if the lifetime distribution is known, the lapse indices for any time period are known.

A complete exposition of these structural relationships and practical implications of it must
be investigated further.

Although the methodology in this thesis is developed specifically for the insurance industry, it may be applied in the normal context of research and scientific decisionmaking, that includes for example survival distributions for the medical, biological, engineering, econometric and sociological sciences.

The potential for extending the methodology to other realistic practical application is unlimited. This can be to the advance of the insurance industry in general. The models should reflect an interactive adaptability for direct application in practice by salesforce (the marketing people on ground level), as well as for actuarial planning.

Abstract

Fitting of survival functions for grouped data on insurance policies

by

Elizabeth Magrietha Louw

Supervisor:  Professor N.A.S. Crowther
Degree:  Ph D

The aim of the research is the statistical modelling of parametric survival distributions of grouped survival data of long- and short-term policies in the insurance industry, by means of a method of maximum likelihood estimation subject to constraints.

This methodology leads to explicit expressions for the estimates of the parameters, as well as for approximated variances and covariances of the estimates, which gives exact maximum likelihood estimates of the parameters. This makes direct extension to more complex designs feasible.

The statistical modelling offers parametric models for survival distributions, in contrast with non-parametric models that are used commonly in the actuarial profession. When the parametric models provide a good fit to data, they tend to give more precise estimates of the quantities of interest such as odds ratios, hazard ratios or median lifetimes. These estimates form the statistical foundation for scientific decisionmaking with respect to actuarial design, maintenance and marketing of insurance policies.

Although the methodology in this thesis is developed specifically for the insurance industry, it may be applied in the normal context of research and scientific decisionmaking, that includes for example survival distributions for the medical, biological, engineering, econometric and sociological sciences.

Die doelwit van die navorsing is die statistiese modellering van parametriese oorlewingsverdelings van gegroepeerde oorlewingsdata van lang- en korttermyn polisse in die versekeringsbedryf, deur middel van 'n metode van maksimum aanneemlikheidsberaming onderworpe aan beperkings.

Hierdie metode lei tot eksplisiete uitdrukings vir die beramings van die parameters, asook vir benaderde variasies en kovariansies van die beramers, wat eksakte maksimum aanneemlikheidsberamings van die parameters gee. Dit maak direkte uitbreiding na meer komplekse ontwerpe moontlik.

Die statistiese modellering bied parametriese modelle vir oorlewingsverdelings, in teenstelling met nie-parametriese modelle wat algemeen in die aktuariële professie gebruik word. Indien die parametriese modelle 'n goeie passing by die data gee, sal hulle meer akkurate beramings van die hoeveelhede van belang, soos kruisproduukverhoudings, risikoverhoudings of mediana leeftye gee. Hierdie beramings vorm die statistiese grondslag vir wetenskaplike besluitneming met betrekking tot aktuariële ontwerp, onderhoud en bemarking van versekeringspolisse.

Alhewel die metodologie in hierdie tesis spesifiek vir die versekeringsbedryf ontwikkel is, kan dit in die normale konteks van navorsing en wetenskaplike besluitneming, wat byvoorbeeld oorlewingsverdelings vir die mediese, biologiese, ingenieurswese, ekonometriese en sosiologiese wetenskappe insluit, toegepas word.
