Abstract

Recent studies suggest that facial attractiveness indicates immune responsiveness in men and that this relationship is moderated by stress hormones which interact with testosterone levels. However, studies testing whether facial attractiveness in women signals their immune responsiveness are lacking. Here we photographed young Latvian women, vaccinated them against hepatitis B and measured the amount of specific antibodies produced, cortisol levels and percentage body fat.

Latvian men rated the attractiveness of the women's faces. Interestingly, in women immune responsiveness (amount of antibodies produced) did not predict facial attractiveness. Instead, plasma cortisol level was negatively associated with attractiveness, indicating that stressed women look less attractive. Fat percentage was curvilinearly associated with facial attractiveness, indicating that being too thin or too fat reduces attractiveness. Our study suggests that in contrast to men, facial attractiveness in women does not indicate immune responsiveness against hepatitis B, but is associated with two other aspects of long-term health and fertility: circulating levels of the stress hormone cortisol and percentage body fat.

Keywords: beauty; cortisol; humans; immune; mate choice; sexual selection.

1. INTRODUCTION

The growing field of evolutionary psychology reports a large body of evidence to suggest that standards of beauty are not arbitrary cultural conventions, pointing to, for example, cross cultural agreement in preferences for cues to health and fertility[1]. Furthermore, a number of studies suggest that facial preferences emerge early in childhood, before any cultural standards of beauty are likely to be assimilated, suggesting we have a strong inborn universal standard of facial beauty [2]. Evolutionary psychologists interpret preferences as strategies evolved due to the selective benefits accrued to those who chose their mates based on these criteria (reviewed in [3]). To argue that such preferences are adaptive, however, it is necessary to show that preferred traits serve as cues to fecundity, health or other traits that enhance fitness, and contribute to higher reproductive success.

Studies linking facial attractiveness and health records in men, however, have found only weak or no association between facial attractiveness and health (reviewed in [3]). Recently

Rantala et al [4] found that men's ability to produce antibodies in response to the hepatitis B vaccine correlated positively with facial attractiveness, suggesting that men's facial attractiveness indicate immunity in humans. Thus, by choosing men with attractive faces as partners women may get direct benefits by avoiding contagion and indirect benefit by increasing health and immunity of their offspring. Since in humans both sexes are choosy, one could predict that female facial attractiveness may also be associated with immune defense and sex hormone levels. However to our knowledge studies testing association between female facial attractiveness, immune defense and stress hormone levels are lacking. Studies linking facial attractiveness with indices of health have led to mixed results: while certain studies have found some evidence that facially attractive women are healthier [5,6,7], other studies have found no association [8,9,10]. Rantala et al [11] found that the link between facial attractiveness and immune response in men was mediated by their facial adiposity, not their masculinity (facial masculinity was however associated with immune response, independently of facial adiposity). Thus, we could expect that adiposity in women is associated with the strength of immunity and attractiveness. The aim of this study was to test whether facial attractiveness in women is associated with the strength of their immune response, circulating levels of the stress hormone cortisol and adiposity.

2. METHODS

(a) Participants

52 Latvian women (mean age = 20.40, SD = 1.24; a subset of 65 women that completed all aspects of the study) not taking hormonal contraception and who reported a normal menstrual cycle participated in the study. They were instructed to visit the laboratory during the fertile phase of their menstrual cycle (20-14 days before the onset of their next period of menstrual bleeding) between

09:00 and 11:00 am. This method of assigning women to groups according to fertility is based on the assumption that the luteal phase lasts 14 days and that the fertile phase does not exceed 6 days [12]. Facial photographs were taken in standardized lighting conditions against a common background. We measured each participant's percentage body fat by using Omron Body Composition Monitor BF500.

(b) Immune and hormone assays

We measured the production of anti-hepatitis B surface antigen (anti-HBsAg) after hepatitis B vaccination. All participants received two doses of the Engerix B vaccine (manufactured by Glaxosmithkline). Before the first vaccination, we collected 6 ml of venous blood to measure the baseline level of antibodies and hormone levels. One month after the vaccination we again collected venous blood to measure antibody production after which participants received their second dose. One month after the second vaccination we again collected venous blood to measure antibody production. Since only 19 out of 52 women produced antibodies after the first dose but 49 out of 52 women produced antibodies after second dose, we used only the amount of antibodies produced after second vaccination in statistical analyses. Cortisol levels were measured from plasma samples taken during the first testing session (when a facial photograph was also taken) (for more detailed methods see Supplementary material). The design of the study was approved by the Research Ethics Committee of the University of Daugavpils, Latvia.

(c) Facial rating

18 heterosexual men from the University of Daugavpils, Latvia (mean age = 21.7 years, SD = 1.53) rated women's facial attractiveness. Photographs were presented in random order on a computer screen and participants were asked to rate the attractiveness of each face. Attractiveness ratings

were recorded on an 11-point scale (-5 = very unattractive, 0 = neutral and +5 = very attractive).

After the trial, each participant was given a brief questionnaire to fill out, asking about his age, the ethnic origin of his mother and father, and sexual orientation. Inter-rater reliability was very high for facial attractiveness (Cronbach α = 0.90), so average attractiveness scores for each female were computed.

Results

Bivariate scatterplots indicate that cortisol and Hepatitis B antibody levels are linearly related to attractiveness, while percentage body fat shows a curvilinear relationship with attractiveness; women with an intermediate level of body fat was rated more attractive than women who had a low or high level of body fat. Cortisol and percentage fat and percentage fat² was significantly correlated with attractiveness, while Hepatitis B antibody response was not (Table 1). We fitted a

Table 1 Pearson's correlations between all variables.

	Attractiveness	Antibody response	Cortisol	Percentage fat
Attractiveness	-			
Antibody response	-0.006	-		
Cortisol	-0.384**	-0.084	-	
Percentage fat	-0.407**	-0.003	0.098	-
Percentage fat ²	-0.481***	-0.041	0.124	0.977***

* p≤0.05, **p≤0.01, ***p≤0.001. N=52. Percentage fat² was included because of the curvilinear relationship between percentage fat and attractiveness.

simultaneous linear regression with attractiveness as the dependent variable and cortisol, Hepatitis B antibody response, percentage body fat and percentage body fat² as independent variables. Using Mahalanobis distance, we identified one multivariate outlier according to the p < 0.001 criterion [13]. The outlier individual was deleted from the analysis. Collinearity diagnostics identified multicollinearity (Condition index = 45.07; with two variable values above 0.5) between percentage

fat and percentage fat², which was solved by centering the values as recommended by Tabachnick and Fidell ([13]; percentage fat was centered before calculating percentage fat²). Using Mahalanobis distance, we identified one multivariate outlier according to the $p < 0.001$ criterion [13]. The outlier individual was deleted from the analysis. The overall model significantly predicted attractiveness ($F=8.46$, $p<0.001$, $R^2=0.42$). Cortisol levels, percentage fat and percentage fat² significantly predicted female facial attractiveness, while Hepatitis B antibody response did not (Table 2).

Table 2. Regression analysis of facial attractiveness judgements.

	β	t	p	Effect size
Cortisol	-0.003	-2.710	0.009	-0.368
Percentage fat	-0.065	-4.016	<0.001	-0.505
Percentage fat ²	-0.004	-3.268	0.002	-0.430
Antibody response	0.000	-0.955	0.345	-0.138

4. DISCUSSION

In contrast to findings in men [4], we found that women's immune response (i.e. ability to produce antibodies) is not associated with their facial attractiveness. Thus, there seems to be sex difference in association between immune defense and facial attractiveness in humans. However, it would be premature to say that the facial attractiveness does not signal the strength of immune defense in women, because the immune system is complex and different components of the immune system trade-off with each other (e.g., the Th1 and Th2 arms of the adaptive immune system)[14] . It is

possible that facial attractiveness signals a different arm of the immune defense in women than men. This remains to be tested in future studies.

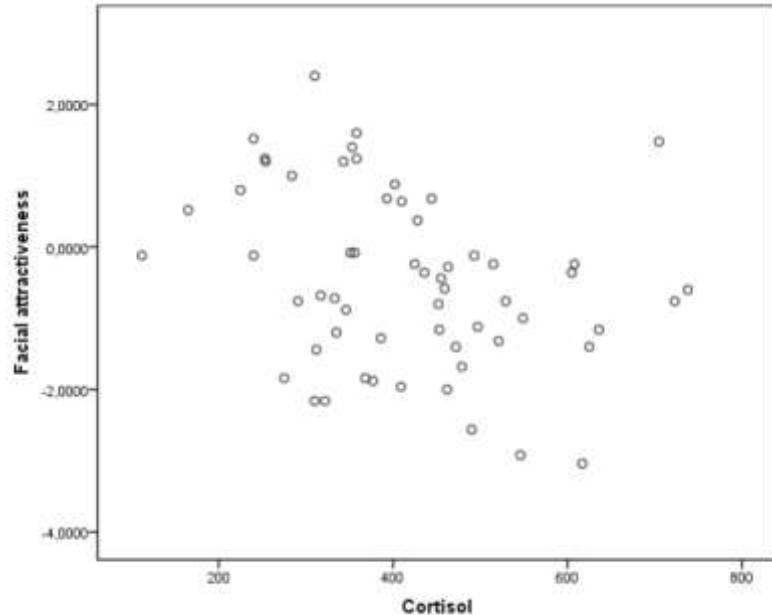

Fig 1. Correlation between facial attractiveness and plasma cortisol levels in women.

Interestingly, facial attractiveness correlated negatively with plasma cortisol level suggesting that stress reduces attractiveness in women (Figure 1). This supports previous findings from male faces, which show that cortisol is inversely related to facial attractiveness [15,16]. This has been interpreted as a mediator of condition dependent cues in the face (e.g. to health) or as a signal of the ability to cope with stressors [15,16]. Perhaps, then, low levels of cortisol also signal health in female faces. This would be consistent with many studies in humans that have found that stress has strong negative effect on health including immune function, heart disease and susceptibility to cancer etc. [17]. An alternative explanation is that facial attractiveness signals reproductive potential [18], which is mediated partly by stress hormones, because many studies have demonstrated that stress disturbs fertility through the inhibition of the hypothalamic-pituitary-gonadal axis leading to anovulation or luteal dysfunction [19].

Consistent with previous studies [20] , we found that body fat shows a significant curvilinear relationship with facial attractiveness. Facial attractiveness therefore has some association with long-term health and fertility. It is well known that obese and overweight individuals have more health problems compared to normal-weight individuals [20,21]. Furthermore, body fat is associated with fertility, because both underweight and overweight women have reduced fertility compared to normal weight women [22] and Tinlin et al [22] found a significant negative correlation between rated facial adiposity and the sex hormone progesterone. Interestingly, in contrast to our findings in men [11] , women's adiposity did not correlate with immune responsiveness. Thus, there also seems to be a sex difference in the association between adiposity and immune function.

In summary, we found no association between female facial attractiveness and immune responsiveness in terms of hepatitis B antibody production. We did, however, find a significant association between female facial attractiveness and two other aspects of long-term health and fertility, plasma cortisol levels and percentage body fat.. Together with previous studies our study therefore suggests that facial attractiveness in women may not signal general immunocompetence, but maybe more likely long-term health and fertility.

The study was funded by Academy of Finland to MJR. FRM was supported by a travel grant of the Carnegie Trust for the Universities of Scotland. VC was funded by a scarce skills postdoctoral fellowship from the South African National Research Foundation.

Supplementary material

Participants

Participants were students from the University of Daugavpils who received 10 Lats (ca. 14 Euros) and free vaccination for participating in the experiment. We explained the purpose of the study to each participant, after which they gave a written consent to us. All women were without make up when photographed with hair combed backwards. Participants were asked to maintain a neutral facial expression and to keep their mouths closed. The size of image was controlled by taking photographs from a fixed distance (180 cm) with Nikon D50 digital camera. At least three facial photographs were taken of each participant, and the best one selected (based on quality, position of the subject, a closed mouth, open eyes, and neutral expression).

Immune and hormone assays

Blood samples were centrifuged immediately after collection, plasma separated and stored at -80 °C. Levels of anti-HBsAg and hormones were assessed at the E. Gulbis Laboratory, Daugavpils, Latvia. To determine serum hepatitis B surface antigen (anti-HBs) levels, the commercially available AxSYM® AUSAB® microparticle enzyme immunoassay (MEIA) was used according to the manufacturer's instructions. Anti-HBsAg concentrations were expressed in mIU/ml (For more detailed methods see Rantala et al [23]). *Mean intra-assay CV for hepatitis B surface antigen (anti-HBsAg) levels was 2.9%, the lower level of detection was 2 mIU/mL and the analytical range was 2-1000 mIU/mL. Six participants expressed anti-HBsAg prior to vaccination and they were excluded from the data.* Mean intra-assay CV for plasma cortisol levels was 3.86%, the method lower limit of detection was 0.5 nmol/L and the analytical range was 0.5-1750 nmol/L. We attained cortical levels (417.17 (134.6) nmol/L) for all participants.

Statistical analyses

Prior to analysis, all variables were examined for accuracy of data entry, missing values, outliers, normality of their distributions and pairwise linearity [1]. We determined whether cortisol, percentage fat and Hepatitis B antibody response significantly predicted attractiveness by fitting a simultaneous linear regression. All statistical analyses were performed in SPSS 20. All variables were normally distributed (two-tailed critical z score = ± 3.29 , $p = 0.001$) and without univariate outliers at $p < 0.001$ (two-tailed critical z score = ± 3.29 ; [1]). Collinearity diagnostics identified multicollinearity (Condition index = 45.07; with two variable values above 0.5) between percentage fat and percentage fat², which was solved by centering the values as recommended by Tabachnick and Fidell [1].
