A Historical Analysis of the US Stock Price Index Using Empirical Mode Decomposition over 1791–2015

Aviral K. Tiwari, Arif B. Dar, Niyati Bhanja, and Rangan Gupta

Abstract
In this paper, the dynamics of Standard and Poor's 500 (S&P 500) stock price index is analysed within a time-frequency framework over a monthly period 1791:08–2015:05. Using the Empirical Mode Decomposition technique, the S&P 500 stock price index is divided into different frequencies known as intrinsic mode functions (IMFs) and one residual. The IMFs and the residual are then reconstructed into high frequency, low frequency and trend components using the hierarchical clustering method. Using different measures, it is shown that the low frequency and trend components of stock prices are relatively important drivers of the S&P 500 index. These results are also robust across various subsamples identified based on structural break tests. Therefore, US stock prices have been driven mostly by fundamental laws rooted in economic growth and long-term returns on investment.

1. Introduction

In recent years, analyses of stock prices within the time-frequency framework have attracted a lot of attention from academicians and market practitioners. The intrinsic complexities of the stock markets have made them least worthy of analysis using the conventional time-domain tools. The obvious reason for this is that stock prices are determined by traders, who deal at different frequencies. While institutional investors and central banks constitute the low-frequency traders, speculators and market makers fall into the category of high-frequency traders in stock markets. Price formation in the stock markets can be attributed to trading by heterogeneous traders within different frequencies. Therefore, some appealing events may remain hidden under different frequencies when stock prices are analysed within the time-domain framework.

In the literature of financial economics, a number of frequency-based approaches have been used to unravel the hidden characteristics of financial time series. Zhang et al. (2008) used the Empirical Mode Decomposition (EMD) to unravel the price characteristics of crude oil at different frequencies. Zhu et al. (2015) analysed price formation in the carbon markets using the EMD. Using wavelet-based approaches, studies like Tiwari et al. (2012, 2013), and Chang et al. (2015), and references cited therein, used wavelet decompositions to study the behaviour of financial variables like oil prices, exchange rates, inflation and stock prices at different frequencies. Nevertheless, EMDs have not to date been used to study the behaviour of stock prices.

Therefore, for this paper we conducted, for the first time, a time-frequency analysis using EMDs for Standard & Poor's 500 (S&P 500) index, covering the long monthly sample of 1791:08-2015:05. This allowed us to determine the various frequency components that have driven stock prices in the US over a prolonged historical sample. EMDs have an advantage over wavelets because their decompositions are based on local characteristic time scales, and have the characteristic of being self-adapting. We attempted to identify the frequencies that have a substantial impact on stock prices. The Ensemble EMD (EEMD), introduced by Huang et al. (1998), was used to decompose the stock price data into different intrinsic modes. The IMFs and the residual extracted were then reconstructed into high-frequency, low-frequency and trend components using the hierarchical clustering method. Different measures were then used to assess the importance of each frequency for the overall stock price series.
The rest of the scheme according to which this paper is organized is as follows. Section 2 provides the information about the methodology followed in the paper. Section 3 provides a discussion on the data and results, and section 4 concludes, with the main findings.

2. **Methodology**

An EMD algorithm for extracting Intrinsic Mode Functions (IMFs) was followed as:

In the first step, the minima and maxima of a time series \( x(t) \) were identified. Then with the cubic spline interpolation upper \( e_{\text{min}}(t) \) and lower \( e_{\text{max}}(t) \) envelopes were generated. In the third step, the point-by-point mean \( (m(t)) \) was calculated from the lower and upper envelopes as: \( m(t) = \frac{e_{\text{min}}(t) + e_{\text{max}}(t)}{2} \). The mean form time series was calculated in step 4, and \( d(t) \) as the difference of \( x(t) \) and \( m(t) \) was calculated as \( d(t) = x(t) - m(t) \). The properties of \( d(t) \) were checked in step 5. If, for example, it was an IMF, the \( ith \) IMF was denoted by \( d_i(t) \). The \( x(t) \) was replaced by the residual, given as: \( r(t) = x(t) - d(t) \). Often the \( ith \) IMF was denoted by \( c_i(t) \), where \( I \) was interpreted as index. If \( d(t) \) was not an IMF, it was replaced by \( d(t) \). These five steps were repeated until the residuals satisfied some conditions known as stopping criteria.2

Contrary to the EMD, the Ensemble EMD proposed by Wu and Huang (2009) avoids the limitation of the mode mixing associated with EMD. The procedure involves an additional step of adding white noise series to targeted data, followed by the decomposition to generate the IMFs. The procedure was repeated by adding different white noise series each time to generate the Ensemble IMFs from the decompositions as an end product.

3. **Results and Discussion**

Our analysis is based on a historical data set of US stock prices. The monthly data on the S&P 500, covering the period 1791:08 to 2015:05 was obtained from the Global Financial Database (GFD). The natural logarithmic values of the data have been plotted in Figure A1, in the Appendix.

Through EEMD, four data samples of the US stock prices were decomposed into (IMFs) and residuals. The data sets include the full sample ranging from 1791:08 to 2015:05, and three subsamples ranging from 1791:08 to 1862:12, 1863:01 to 1940:04 and 1940:05 to 2015:05. The subsamples were identified by applying the Bai and Perron (2003) test of structural

---

2 For the stopping criteria, please refer to Zhang et al. (2008).
breaks in both mean and trend to the natural logarithms of the S&P 500 stock index. The division of the data into three subsamples gives a better idea of how the dynamics of the US stock market have evolved over time, and added to the robustness of the results. The IMFs along with the residual are shown in Figures A2, A3, A4 and A5, in the Appendix. The IMFs were generated in the order of highest to lowest frequency. The IMFs were then analysed by three measures. First, the mean period of each IMF – defined as the value extracted by dividing the total number of points by the number of peaks in the dataset – was calculated. Second, the pairwise correlation between the original data series and the IMFs was estimated by using a Pearson and Kendall rank correlation. Third, the variance and variance percentage of each IMF were calculated. These results are shown in Tables 1, 2, 3 and 4.

Both the Pearson and Kendall coefficients between the original and high-frequency IMFs are low. However, the correlation is higher between the low-frequency IMFs and the original series. It can also be seen that the variances between lower (higher) frequencies contribute substantially (less) to the total variability.

Within these decompositions, however, the residues are the dominant modes. Their contribution to the total variability is highest, and the correlation with the original data series is also highest. The residue referred to as the deterministic long-term trend by Huang et al. (1998) indicates a very high correlation and accounts for a very high variability in the original series. A noteworthy observation here is that the correlation of the long-term trend with the data and the variability contribution increases for the more recent samples. Since the continuing increasing trend of the US stock market is consistent with the development of the US economy over the decades, it can be said that the long-term price behaviour of US stocks has been determined by the long-term growth of the US.

We then used a hierarchical clustering analysis, and subsequently the Euclidean distance to group the IMFs and residuals into their high-frequency, low-frequency and trend components. The extracted components for all the time series are shown in Figure 1.

---

Figure 1. Three components of the S&P 500

---

3We have followed Zhu et al. (2013) to extract the different time series components. For the sake of brevity, we do not show the results here; however, they can be produced on request.
Each component in these diagrams shows the distinct features. For example, the residuals show the slow variation around the long-term trend. Hence, it is considered as a long-term trend of a time series. The effect of medium to high frequencies was captured by two other frequencies, with the high frequency components reflecting the effect of short-term market fluctuations. For the moment of observed stock price series, the most important components are the low-frequency component and the trend. The Pearson and Kendall correlation between the different frequency components and the original series shown in Table 5 vary between samples. For example, they are comparatively higher for the lower frequency and trend components of a time series, especially during the recent periods. This holds for the variance contribution too. The variance contribution is relatively greater from the low frequency and trend components of the time series. This is especially true for the more recent periods. The results obtained are robust to the subsamples. In nutshell, we did not find any evidence of US stock prices having been driven by short-term irrational behaviour. Our results support the view that the US stock market is driven mostly by fundamentals, which, in turn, are most likely rooted in economic growth and long-term returns on investment (Rapach and Zhou, 2013).

4. Conclusion

In this paper, the data of the S&P 500 index was decomposed into a number of IMFs and residuals, using the EEMD. The monthly data sets include the full sample ranging from 1791:08 to 2015:05 and three subsamples for the US stock prices: 1791:08 to 1862:12, 1863:01 to 1940:04 and 1940:05 to 2015:05. The division of the data into three subsamples gave a better idea of how the dynamics of the US stock market evolved over time, as well as the robustness of the results. The IMFs were generated in the order of highest to lowest frequency. The IMFs were analysed by three measures: mean, correlation with the original series and the contribution to the variability of the original series. It is shown that the residuals and low frequency IMFs indicate a very high correlation and account for very high variability in the original series. Also, it was found that the correlation of the long-term trend with the data and the variability contribution increased for the more recent samples. The IMFs and residuals were reconstructed into their high-frequency, low-frequency and trend components for the same full and subsamples. Again, it was found that the Pearson and Kendall correlation is comparatively higher for the lower-frequency and trend components of a time series, especially during the recent periods. The variance contribution was also found

to be relatively greater from the low-frequency and trend components of the time series. The subsample results were found to corroborate the full-sample results. Therefore, it is concluded that, in general, US stock prices are not driven by the short-term irrational behaviour of investors, but seem to be driven mostly by fundamentals; though, it is true that there have been episodes of bubbles, as indicated by Phillips et al. (2015).
