THE ROLE OF NEWS-BASED UNCERTAINTY INDICES IN PREDICTING OIL MARKETS: A HYBRID NONPARAMETRIC QUANTILE CAUSALITY METHOD

 d University of Pretoria

ABSTRACT

A recent literature emphasizes the role of news-based economic policy uncertainty (EPU) and equity market uncertainty (EMU) as drivers of oil-price movements. Against this backdrop, this paper uses a $k$-th order nonparametric quantile causality test, to analyze whether EPU and EMU predicts stock returns and volatility. Based on daily data covering the period of 2nd January, 1986 to 8th December, 2014, we find that, for oil returns, EPU and EMU have strong predictive power over the entire distribution barring regions around the median, but for volatility, the predictability virtually covers the entire distribution, with some exceptions in the tails. In other words, predictability based on measures of uncertainty is asymmetric over the distribution of oil returns and its volatility.

1. **Introduction**

Following the seminal work of Hamilton (1983), a large literature exists that connects oil-price movements (shocks) with recessions and inflationary episodes in the US economy (e.g., see Kang and Ratti, 2013a, b; Antonakakis *et al.*, 2014 for detailed reviews). This, in turn, implies that it is of paramount importance to determine the variables that drives the oil market to properly model and forecast oil price. In this regard, a recently growing literature emphasizes the role of economic policy uncertainty on real activity (e.g., see Bloom, 2009; Colombo, 2013; Jones and Olson, 2013 for detailed reviews), which, in turn, affects oil-price movements (Kang and Ratti, 2013a, b; Antonakakis *et al.*, 2014.). Equity-market uncertainty also feeds into oil-price movements because, as Bloom’s (2009) firm-based theoretical framework notes, equity-market uncertainty affects hiring and investment and, hence, production decisions of firms. In this regard, empirical evidence relating oil price movements and stock market volatility can be found in Kang *et al.*, (2015).

Against this backdrop, the objective of this paper is to analyse whether recently developed news-based measures of economic policy uncertainty (EPU) and equity market uncertainty (EMU) by Baker *et al.*, (2013) can predict returns and volatility of oil returns. For our purposes, we employ a modified bivariate quantile causality test that builds combines conditions of the causality-in-quantile test as in Jeong *et al.* (2012) and of the higher-moment *kth*-order nonparametric causality test as in Nishiyama *et al.* (2011). Our empirical analysis utilizes daily data of oil returns and of the EPU and EMU indices spanning the period January 2, 1986 to December 8, 2014.

While conditional mean-based evidence of EPU (mildly and negatively) affecting oil price from structural vector autoregressive (SVAR) models applied to monthly data, can be found in Kang and Ratti (2013a, b) and Antonakakis *et al.*, (2014), to the best of our knowledge, our paper is the first attempt to analyse the importance of both EPU and EMU in
predicting within-sample oil returns and its volatility over the entire conditional distribution of oil returns and volatility. The causality-in-quantile approach employed in our study presents with the following novelties: The causality-in-quantile approach has the following novelties: Firstly, it is robust to misspecification errors as it detects the underlying dependence structure between the examined time series; this could prove to be particularly important, as it is well known (and as we show below) that high-frequency data display nonlinear dynamics. Secondly, via this methodology, we are able to test for not only causality-in-mean (1\textsuperscript{st} moment), but also causality that may exist in the tails of the joint distribution of the variables, which in turn, is particularly important if the dependent variable has fat-tails – something we show below to hold for oil returns. Finally, we are also able to investigate causality-in-variance thereby volatility spillovers, as sometimes even when causality in the conditional-mean might not exist, higher order interdependencies cannot be ruled out. The remainder of the paper is organized as follows: section 2 describes the mathematical context of quantile and higher-moment nonparametric causality, whilst section 3 presents the empirical results. Finally, Section 4 concludes.

2. NONPARAMETRIC QUANTILE CAUSALITY TESTING

We present thereafter a novel methodology for the detection on nonlinear causality via a hybrid approach based on the Nishiyama \textit{et al.} (2011) and Jeong \textit{et al.} (2012) framework. We denote oil returns as $y_t$ and uncertainty index as $x^n_t$, where $n = 1, 2$ denoting EPU and EMU, respectively. The quantile-based causality is defined as follows:

$x^n_t$ does not cause $y_t$ in the $\theta$-quantile with respect to the lag-vector of

$\{y_{t-1}, \ldots, y_{t-p}, x^n_{t-1}, \ldots, x^n_{t-p}\}$ if

$$Q_\theta(y_t|y_{t-1}, \ldots, y_{t-p}, x^n_{t-1}, \ldots, x^n_{t-p}) = Q_\theta(y_t|y_{t-1}, \ldots, y_{t-p})$$

(1)
\( x_t^n \) is a prima facie cause of \( y_t \) in the \( \theta \)-th quantile with respect to \( \{y_{t-1}, \ldots, y_{t-p}, x_{t-1}^n, \ldots, x_{t-p}^n\} \) if
\[
Q_\theta(y_t | y_{t-1}, \ldots, y_{t-p}, x_{t-1}^n, \ldots, x_{t-p}^n) \neq Q_\theta(y_t | y_{t-1}, \ldots, y_{t-p})
\]  
where \( Q_\theta(y_t | \cdot) \) is the \( \theta \)-th quantile of \( y_t \) depending on \( t \) and \( 0 < \theta < 1 \).

Let \( Y_{t-1} \equiv (y_{t-1}, \ldots, y_{t-p}) \), \( X_t^n \equiv (x_{t-1}^n, \ldots, x_{t-p}^n) \), \( Z_t = (X_t^n, Y_t) \), and \( F_{y_t | Z_{t-1}}(y_t | Z_{t-1}) \) and \( F_{y_t | Z_{t-1}}(y_t | Y_{t-1}) \) denote the conditional distribution functions of \( y_t \) given \( Z_{t-1} \) and \( Y_{t-1} \), respectively. The conditional distribution \( F_{y_t | Z_{t-1}}(y_t | Z_{t-1}) \) is assumed to be absolutely continuous in \( y_t \) for almost all \( Z_{t-1} \). If we denote \( Q_\theta(Z_{t-1}) \equiv Q_\theta(y_t | Z_{t-1}) \) and \( Q_\theta(Y_{t-1}) \equiv Q_\theta(y_t | Y_{t-1}) \), we have \( F_{y_t | Z_{t-1}}(y_t | Z_{t-1}) = \theta \) with probability one. Consequently, the hypotheses to be tested based on definitions (1) and (2) are:
\[
H_0 = F_{y_t | Z_{t-1}}(Q_\theta(Y_{t-1}) | Z_{t-1}) = \theta = 1
\]  
\[
H_0 = F_{y_t | Z_{t-1}}(Q_\theta(Y_{t-1}) | Z_{t-1}) = \theta < 1
\]

Jeong et al., (2012) employs the distance measure \( J = \varepsilon_t E(\varepsilon_t | Z_{t-1}) f_Z(Z_{t-1}) \) where \( \varepsilon_t \) is the regression error term and \( f_Z(Z_{t-1}) \) is the marginal density function of \( Z_{t-1} \). The regression error \( \varepsilon_t \) emerges based on the null in (3), which can only be true if and only if \( E[1\{y_t \leq Q_\theta(Y_{t-1}) | Z_{t-1}\}] = \theta \) or equivalently \( 1\{y_t \leq Q_\theta(Y_{t-1})\} = \theta + \varepsilon_t \), where \( 1\{\cdot\} \) is an indicator function. Jeong et al. (2012) specify the distance function as follows:
\[
J = E \left[ \left( F_{y_t | Z_{t-1}}(Q_\theta(Y_{t-1}) | Z_{t-1}) - \theta \right)^2 f_Z(Z_{t-1}) \right]
\]

In Eq. (3), it is important to note that \( J \geq 0 \), i.e., the equality holds if and only if \( H_0 \) in (5) is true, while \( J > 0 \) holds under the alternative \( H_1 \) in Eq. (4). Jeong et al., (2012) show that the feasible kernel-based test statistic for \( J \) has the following form:
\[
\hat{J}_T = \frac{1}{T(T-1)h^{2p}} \sum_{t=p+1}^T \sum_{s=p+1}^T K \left( \frac{Z_{t-1} - Z_{s-1}}{h} \right) \hat{\varepsilon}_t \hat{\varepsilon}_s
\]
where $K(\cdot)$ is the kernel function with bandwidth $h$, $T$ is the sample size, $p$ is the lag-order, and $\hat{\varepsilon}_t$ is the estimate of the unknown regression error, which is estimated as follows:

$$\hat{\varepsilon}_t = 1\{y_t \leq \hat{Q}_\theta(Y_{t-1})\} - \theta$$

(7)

$\hat{Q}_\theta(Y_{t-1})$ is an estimate of the $\theta$-th conditional quantile of $y_t$ given $Y_{t-1}$. Below, we estimate $\hat{Q}_\theta(Y_{t-1})$ using the nonparametric kernel method as:

$$\hat{Q}_\theta(Y_{t-1}) = \hat{F}_{y_t|Y_{t-1}}^{-1}(\theta|Y_{t-1})$$

(8)

where $\hat{F}_{y_t|Y_{t-1}}(y_t|Y_{t-1})$ is the Nadarya-Watson kernel estimator given by:

$$\hat{F}_{y_t|Y_{t-1}}(y_t|Y_{t-1}) = \frac{\sum_{s=p+1}^{T} L\left(\frac{Y_{t-1} - Y_{s-1}}{h}\right) 1(y_s \leq y_t)}{\sum_{s=p+1}^{T} L\left(\frac{Y_{t-1} - Y_{s-1}}{h}\right)}$$

(9)

with $L(\cdot)$ denoting the kernel function and $h$ the bandwidth.

In an extension of the Jeong et al., (2012) framework, we develop a test for the 2nd moment. In particular, we want to test the causality running from EPU or EMU to the volatility of oil returns. Causality in the $k$-th moment generally implies causality in the $m$-th moment for $k < m$. Firstly, we employ the nonparametric Granger quantile causality approach by Nishiyama et al., (2011). In order to illustrate the causality in higher order moments, consider the following process for $y_t$:

$$y_t = g(Y_{t-1}) + \sigma(Y_{t-1}^{\alpha})\varepsilon_t$$

(10)

where $\varepsilon_t$ is a white noise process; and $g(\cdot)$ and $\sigma(\cdot)$ are unknown functions that satisfy certain conditions for stationarity. However, this specification does not allow for Granger-type causality testing from $X_{t-1}^{\alpha}$ to $y_t$, but could possibly detect the “predictive power” from $X_{t-1}^{\alpha}$ to $y_t^2$ (i.e., volatility of the returns series under consideration, which in our case is oil returns volatility)\(^1\) when $\sigma(\cdot)$ is a general nonlinear function. Hence, the Granger causality-

\(^1\) Measuring volatility of a series as squared returns, especially related to the oil markets have been discussed in detail by Lux et al., (forthcoming).
in-variance definition does not require an explicit specification of squares for $X_{t-1}^2$. We re-formulate Eq. (10) into a null and alternative hypothesis for causality in variance as follows:

\[
H_0 = P \{ F_{y_t^2|Z_{t-1}} \{ Q_\theta (Y_{t-1}) | Z_{t-1} \} = \theta \} = 1 \quad (11)
\]

\[
H_1 = P \{ F_{y_t^2|Z_{t-1}} \{ Q_\theta (Y_{t-1}) | Z_{t-1} \} = \theta \} < 1 \quad (12)
\]

To obtain a feasible test statistic for testing the null in Eq. (10), we replace $y_t$ in Eq. (6) - (9) with $y_t^2$. Incorporating the Jeong et al., (2012) approach we overcome the problem that causality in the conditional 1st moment (mean) imply causality in the 2nd moment (variance). In order to overcome this problem, we interpret the causality in higher order moments using the following model:

\[
y_t = g(X_{t-1}^p, Y_{t-1}) + \varepsilon_t \quad (13)
\]

Thus, higher order quantile causality can be specified as:

\[
H_0 = P \{ F_{y_t^k|Z_{t-1}} \{ Q_\theta (Y_{t-1}) | Z_{t-1} \} = \theta \} = 1 \quad \text{for } k = 1, 2, \ldots, K \quad (14)
\]

\[
H_1 = P \{ F_{y_t^k|Z_{t-1}} \{ Q_\theta (Y_{t-1}) | Z_{t-1} \} = \theta \} < 1 \quad \text{for } k = 1, 2, \ldots, K \quad (15)
\]

Integrating the entire framework, we define that $X_{t}^p$ Granger causes $y_t$ in quantile $\theta$ up to $K$-th moment utilizing Eq. (14) to construct the test statistic of Eq. (6) for each $k$. However, it can be shown that it is not easy to combine the different statistics for each $k = 1, 2, \ldots, K$ into one statistic for the joint null in Eq. (14) because the statistics are mutually correlated (Nishiyama et al., 2011). To efficiently address this issue, we include a sequential-testing method as described Nishiyama et al. (2011) with some modifications. Firstly we test for the nonparametric Granger causality in the 1st moment ($k = 1$). Rejecting the null of non-causality means that we can stop and interpret this result as a strong indication of possible Granger quantile causality-in-variance. Nevertheless, failure to reject the null for $k = 1$, does not automatically lead to no-causality in the 2nd moment, thus we can still construct the tests for $k = 2$. Finally, we can test the existence of causality-in-variance, or the causality-in-mean
and variance successively. The empirical implementation of causality testing via quantiles entails specifying three important choices: the bandwidth $h$, the lag order $p$, and the kernel type for $K(\cdot)$ and $L(\cdot)$ in Eq. (6) and (9) respectively. In our study, the lag order (9 and 5 respectively) is determined using the Schwarz Information Criterion (SIC) under a VAR comprising oil returns and EPU or EMU respectively. The SIC being parsimonious when it comes to choosing lags compared to other alternative lag-length selection criterion, helps us to prevent issues of overparametrization commonly associated with nonparametric approaches. The bandwidth value is selected using the least squares cross-validation method. Lastly, for $K(\cdot)$ and $L(\cdot)$ we employ Gaussian-type kernels.

3. DATA ANALYSIS AND EMPIRICAL RESULTS

In this section, we empirically investigate the ability of EPU and EMU in predicting oil returns and volatility of oil returns over various quantiles, using data covering the period of 2nd January, 1986 to 8th December, 2014, with the start and end dates being purely driven by data availability. We use the EMU and the EPU indices, developed by Baker et al., (2013), as two measures of the degree of uncertainty in the US economy. Data on these two measures of uncertainty come from the website: www.policyuncertainty.com. The daily news-based EPU index uses newspaper archives from Access World News Bank service. The primary measure for this index equals the number of articles that contain at least one term from each of 3 sets of terms, namely, economic or economy, uncertain or uncertainty, and legislation or deficit or regulation or congress or Federal Reserve or White House. Using the same news source, the EMU index searches for articles containing the terms uncertainty or uncertain, economic or

\footnote{Further details are available at: http://www.policyuncertainty.com/us_daily.html.}
economy, and one or more of the following terms: equity market, equity price, stock market, or stock price.\textsuperscript{3} Note that, we work with natural logarithmic values of EPU and EMU.

We use the daily spot price on West Texas Intermediate (WTI) crude to represent the oil market. These data come from the FRED database at the Federal Reserve Bank of St. Louis available at: \url{http://research.stlouisfed.org/fred2/}. We express oil prices as returns (i.e., the natural logarithmic difference expressed in percentage) to ensure stationarity.\textsuperscript{4} Our effective sample therefore, starts on 3\textsuperscript{rd} January, 1986 and gives us a total of 7299 observations to work with. Note that, instead of using the VIX,\textsuperscript{5} a popular measure of the implied volatility of S&P 500 index options, we use the news-based measure of EMU index to ensure that both our measures of uncertainty are derived in a similar method (i.e., news articles-based and, hence, the results, in terms of their relationship with oil, are comparable).\textsuperscript{6}

\textsuperscript{3} Further details are available at: \url{http://www.policyuncertainty.com/equity_uncert.html}.

\textsuperscript{4} Not surprisingly, standard unit root tests reveal that oil price is a unit root process, while oil returns is stationary. On the other hand, EMU and EPU are found to be stationary. Complete details on the unit root tests are available upon request from the authors.

\textsuperscript{5} Often referred to as the fear index or the fear gauge, it represents one measure of the Market’s expectation of stock-market volatility over the next 30 day period.

\textsuperscript{6} As indicated at: \url{http://www.policyuncertainty.com/equity_uncert.html}, the EMU exhibits a contemporaneous daily correlation with the VIX of over 0.3.
The summary statistics of the variables have been reported in Table 1. As can be seen, oil returns and EPU are skewed to the left, EMU skewed to the right, with all the variables having excess kurtosis. The Jarque-Bera test overwhelmingly rejects the null of normality, and this evidence of fat-tails in the variables provide us the preliminary motivation to use causality-in-quantiles test rather than standard linear Granger causality test based on the conditional mean. Note that EMU has higher volatility than EPU, which is understandable, given that it captures uncertainty in financial markets.

Though our primary objective is to analyse the predictability of EPU and EMU for oil returns and volatility, for the sake of comparison, we also investigated whether EPU and EMU can predict oil returns by conducting standard linear Granger causality tests based on VAR models with nine and five lags for EPU and EMU. As can be seen from Table 2, the null hypothesis of EPU (EMU) does not Granger cause oil returns was rejected at the 1% (10%) level of significance.

Note: VAR(9) and VAR(5) are respectively used for oil returns and EPU, and oil returns and EMU.

Next, to motivate the use of the nonparametric quantile-in-causality approach, we statistically investigate the possibility of nonlinearity in the relationship between oil returns and EPU, and oil returns and EMU. To this end, we used the Brock et al. (BDS, 1996) test on the residuals of the oil returns equation of the VAR(9) and VAR(5) models comprising oil returns and EPU and EMU respectively. As can be seen from Table 3, the null hypothesis of iid residuals is strongly rejected at 1% level of significance across various dimensions. Those

Note: Parameter stability tests proposed by Andrews (1993) and Andrews and Ploberger (1994) with the null hypothesis of parameter stability.

results provide evidence of nonlinearities in the data. Next we employed parameter (in)stability testing developed by Andrews (1993) and Andrews and Ploberger (1994) for the oil returns equations in the two VAR models. As can be seen from Table 4, the null of stability was rejected at 1% level of significance by all test-stats i.e., Sup-F, Exp-F and Ave-F. The results were also corroborated by the Bai and Perron (2003) test of multiple structural breaks, which detected four breaks each in the oil returns equation for the EPU- and EMU-based VARs. The break dates are based on the WDMAX test under 1 to M globally determined breaks. As suggested by Bai and Perron (2003), we used a maximum of 5 breaks and trimming of 15%, which resulted in the break dates of 8th August, 1990; 20th May, 1996; 26th March, 2003; and 10th of December, 2008 for the oil returns equation in the VAR with EPU, and 24th October, 1990; 2nd October, 1998; 13th March, 2003; and 26th November, 2008
for the same in the VAR with EMU. So as under the BDS test which detected nonlinearity, existence of structural breaks in the association between oil returns with EPU and EMU, imply that the Granger causality tests based on a linear framework are likely to suffer from misspecification. Given the strong evidence of both nonlinearity and regime changes in the relationships between oil returns and the two measures of uncertainty, we now turn our attention to the causality-in-quantiles test.

Figures 1a and 1b reports the predictive ability of EPU for oil returns and volatility of oil returns, while Figures 2a and 2b does the same based on EMU. As far as predicting oil returns is concerned, the results are quite similar for EPU and EMU across the various quantiles, with the null hypothesis of no causality being rejected for quantiles below 0.40 and above 0.55, and below 0.45 and above 0.55 respectively. As far as predicting the volatility is concerned, the situation is quite similar again, barring a slight difference at the higher end of the distribution. While for EPU, the null is rejected for all quantiles above 0.15, for EMU the null is rejected between quantiles 0.20 and 0.85. Overall, our results show that, as far as oil returns are concerned, EPU and EMU has predictability except around a region close to the median, but for volatility, the predictability virtually covers the entire distribution, with some exceptions in the tails.\(^8\),\(^9\)

The results tend to suggest that uncertainties related to economic policy and the equity market have predictive information content except around the median of the conditional distribution of oil returns. In other words, uncertainty matters only when the oil market is performing below or above its normal (average) mode, i.e., either in bullish or bearish

\(^8\) We obtained qualitatively similar results when we used oil returns and volatility based on the Brent crude price covering the period of 21\(^{st}\) May, 1987 to 8\(^{th}\) December, 2014. These results are available upon request from the authors.

\(^9\) Oil returns is found to cause the mean of EPU from quantiles 0.25 and above, while its volatility is predicted over the entire conditional distribution. For EMU, oil returns predicts the mean over the entire conditional distribution. As far as volatility of EMU is concerned, oil returns predicts it except around the median and upper quantiles, i.e., beyond 0.80. Note that, since it is difficult to interpret economically what variance of the uncertainty indices imply, we keep these results restricted to this footnote. Complete details of these results are available upon request from the authors.
**Figure 1A:** Quantile Causality Results for the $H_0$: \textit{EPU does not Granger - cause Oil Returns}

![Graph for Figure 1A](image)

**Figure 1B:** Quantile Causality Results for the $H_0$: \textit{EPU does not Granger - cause Oil Return Volatility}

![Graph for Figure 1B](image)
scenarios. In case of the volatility of oil returns, uncertainty in general affects the variance over the entire conditional distribution, i.e., at various phases of the oil market. There are, however, some exceptions, with the economic policy related uncertainty unable to predict volatility of oil returns when the market is in extreme bearish regime. The same structure of predictability of oil returns volatility carries over for the case of equity market related
uncertainty, in addition to the fact that EMU also cannot predict oil market volatility under extreme bullish situations. So, while there is evidence of lack of predictability emanating from measures of uncertainty around the median for oil returns, the same is true for volatility around the tails.

At this stage, it is important to provide an explanation to why we observe these results by looking closely at the data structure and the relationship amongst the variables. First, we point out that the non-rejection ranges of the quantiles for causality in mean corresponds to quantiles between 0.40 and 0.55 for EPU, and between 0.45 and 0.55 for EMU. These quantile ranges correspond to quantiles around the median, that is the center of the conditional distribution of the oil returns. Most of the observations also fall in these quantile ranges. From Table 1, we see that the mean oil return is approximately zero, therefore the non-causality in mean occurs around the zero return ranges. These zero return ranges also correspond to low volatility periods, where markets are optimistic and quite. The changes in both EPU and EMU are also relatively small during the low volatility periods, implying that the information flow is low during these periods. Therefore, during periods where the markets are quite and return is low, low level of information flow do not have any significant impact on the average market return. This happens because, when the volatility is low, response of the average return will also be low and not significant. However, during the high volatility periods where market returns is at extremes (negative or positive) the same level of change in EPU and EMU have significant impact on oil returns. Second, when we consider the causality in variance, we observe that EPU and EMU both have significant impact on almost entire distribution of the conditional variance above the 0.15-th quantile for EPU and between 0.20-th and 0.85-th quantiles for EMU. Noting that the low quantiles of the variance corresponds to zero return ranges of the level of the oil returns, this is well consistent with the causality in mean results. Therefore, changes in EPU and EMU do not also significantly
affect the volatility when the markets are quite and volatility is low, i.e., periods of low average returns. Nonsignificant causality in variance above 0.85-the quantiles for EMU is probably due to very high variance estimates of the tests statistics since not many observations (squared returns) fall into these very extreme ranges for the EMU.

4. Conclusions

There exists a large literature that connects oil-price movements (shocks) with recessions and inflationary episodes in the US economy. Given this, it is important to determine the variables that drive the oil market to. In this regard, a recently growing literature emphasizes the role of uncertainties (economic policy and equity market) as drivers of oil-price movements. Against this backdrop, the objective of this paper is to analyse whether recently developed news-based measures of economic policy uncertainty (EPU) and equity market uncertainty (EMU) can predict returns and volatility of oil returns. For our purpose, we use a bi-variate quantile causality test, which combines causality in quantiles, with a $k$-th order nonparametric Granger causality.

Based on daily data on WTI oil price returns, EPU and EMU, covering the period of 2\textsuperscript{nd} January, 1986 to 8\textsuperscript{th} December, 2014, we find that, as far as oil returns are concerned, EPU and EMU has strong prediction power over the entire distribution barring regions around the median, but for volatility, the predictability virtually covers the entire distribution, with some exceptions in the tails. In other words, uncertainty variables are likely to predict oil returns under extreme situations in the oil market, while volatility is likely to be predicted when the market is relatively calm, i.e., predictability is asymmetric over the distribution of oil returns and its volatility.
As part of future research, it would be interesting to extend our study to forecasting, since it is quite well-accepted that in-sample predictability does not guarantee the same over an out-of-sample (Bekiros et al., 2015).
