Abstract: The developing world has been faced with high rates of unemployment, exacerbated by extended enforced lockdowns due to the pandemic. Pressure is mounting for drastic intervention to accelerate economic growth and to provide employment opportunities. Most of these countries are faced with inadequate road transport facilities in support of economic growth. The construction of high-order roads in support of economic growth requires high degrees of compliance with limited opportunities for increased labour content. However, many of the existing surfaced roads are notoriously lacking periodic preventative maintenance operations needed to preserve the integrity of road surfaces to protect pavement structures against water ingress and resultant rapid deterioration. This article demonstrates the ability of available, proven nanotechnologies to restore the water-resistant properties of already compromised road surfacings. It is shown that traditionally used road products can substantially be improved (in terms of strength properties and resistance to environmental factors) through the addition of applicable nanotechnology modifiers. These modified products can be applied at ambient temperatures, ideally suited for labour intensive applications as demonstrated, showing several examples of actual applications. A combination of modified existing technologies is recommended to partially restore severely compromised road surfacings, especially applicable to secondary and tertiary urban road networks. The implementation of the recommended restoration programmes can go a long way towards road asset preservation, while simultaneously addressing the urgent need for rapid employment generation.

Keywords: nanotechnology applications in road maintenance; preventative road surface maintenance; nanotechnology clear-seals; new-age (nano) modified emulsions (NME); pothole repairs; modified bitumen emulsion slurry seals; hydrophobic modified binder slurries; hydrophobic road surface sealants; labour intensive periodic maintenance; employment through preventative road maintenance

1. Introduction

The developing world is faced with high unemployment statistics, exacerbated by an extended lockdown of economies enforced by the world-wide pandemic. Governments are under increasing pressure from the electorate to create job opportunities with increased expenditure on infrastructure projects and to create an environment for economic growth. A prerequisite for economic growth is a transportation infrastructure supporting economic activities, giving access to markets, etc. Hence, road authorities are also under increasing pressure to increase the labour component of road infrastructure projects. The construction of high-order primary roads in support of economic growth requires a high degrees of compliance with engineering specifications, and it is often difficult to increase the labour content of these projects.

An increase in the labour component of lower-order roads is more easily achieved, where the expected level of service, in line with the number of vehicles to accommodate, is of lesser importance as a component of economic growth. However, an often-overlooked component for increased labour-intensive operations on road networks is the periodic maintenance of the existing surfaced roads. Periodic maintenance (also known as preventative maintenance) is notoriously lacking in numerous countries, often leading to premature distress and the destruction of valuable road infrastructure assets. In the absence of Maintenance Management Systems (MMSs), the integrity of road surfacings is relatively compromised (compared to the original road structure design period) due to the ageing effect (environmental impact) of the surfacing binder, leading to cracking and water ingress into the road pavement structure, which result in accelerated premature distress in the form of cracking, surface disintegration and potholes. In effect, the absence of MMSs can be directly associated with the destruction of valuable state assets (roads) which directly support economic growth.

The introduction of any new disruptive technology [1] in a traditionally well-established industry such as the road industry is usually associated with considerable resistance. This is especially relevant when the new technology is based on the use of relatively new concepts not traditionally associated with the road infrastructure industry, such as nano-silanes, hydrophobicity, nano-polymers and new-age (Nano) modified emulsions (NME). These concepts are all relatively new in the road industry, although most (if not all) of these concepts and products have been used successfully in the built-environment for decades, with some since the 1800s [2–4], to protect stone buildings from the destructive effect of adverse weather (water) conditions. The applicability of proven nanotechnologies had been identified [5] for use in roads more than a decade ago and has been proven in laboratories [6–9] beyond reasonable doubt over the last two decades.

Over the last decade, the use of material-compatible NME technologies for the stabilisation of marginal granular materials has been proven through accelerated pavement testing (APT) [10–12] and in practice [7,13]. Simultaneously, the fundamental requirements [14] for NME products and scientifically based design concepts have been developed and published in international peer-reviewed reputable journals [15,16] to ensure that these technologies can be universally applied without risk to life and the environment. Risks to pavement design engineers are also minimised in terms of future pavement materials behaviour, durability, and cost implications using life-cycle cost analysis incorporation probabilistic theories [17]. The adoption of design concepts incorporating material-compatible NME nanotechnology solutions has been shown to reduce the provision of sustainable road transportation infrastructure by more than 50 per cent [11,12]. The data also show a considerable reduced damage caused by overloading (of high importance in the absence of law enforcement in terms of heavy-vehicle overloading), compared to traditional pavement structural design approaches [11,12].

These same applicable nanotechnologies proven for the construction of road pavement layers are as suitable for the periodic preventative maintenance and protection of existing roads. Road surface maintenance is a well-documented problem, especially in the developing world, where little capacity in terms of sustainable periodic preventative maintenance programmes exist. The expected distress-free durability of bituminous surfacing materials on roads under harsh environmental conditions (exposure to high ultraviolet radiation and high temperature variations normally experienced between the tropics and in the desert areas of the world) are normally much less than the design period of road pavement structures of 20 years or more. If left unattended, in the absence of good MMSs, these road surfaces will develop environmental-related cracking that will soon deteriorate into surface disintegration and roads inundated with potholes in the presence of water and vehicle loading. It follows that any breach in the integrity of the road surface will result in considerable premature structural damage and the effective destruction of considerable investments in road infrastructure. This scenario is all too familiar and common in many parts of the world in dire need of economic development and associated employment opportunities.

Traditionally used preventative maintenance actions are usually associated with the placement of new surfacings (e.g., chip-seals), applying high-temperature bituminous products. In the same vein, traditionally used mixes for pothole repairs, or the re-instatement of surface damage, comes at considerable cost. These “cold-mix” products are notoriously expensive and difficult to use under low-temperature conditions (below 20 °C), resulting in relatively low compacted densities and highly porous surfacings. Hence, water penetration into these reinstated surfacings is relatively easy, with a resultant quick deterioration in condition and the re-appearance of potholes, usually with increased extent and dimensions.

The adoption of proven nanotechnologies for the stabilisation of granular pavement layers [16], also applicable to road surface maintenance, could be key to the reversal of the scenario of road pavement pre-mature distress due to compromised road surfaces. The objectives of this article are to:

- Demonstrate the advantages that can be achieved using applicable, safe nanotechnology solutions for periodic/preventative maintenance, specifically with regard to the quantification of the water-repellent (hydrophobic) ability of these technologies;
- Recommend applicable modified binder products suitable to address road surface distress when the integrity of the road surface has already been compromised, allowing water ingress into the pavement structure and associate development of distress, and
- Demonstrate the suitability of nanotechnology solutions to road preventative and routine road surface restoration activities for labour-intensive applications, creating rapid employment opportunities.

The considerable benefits in terms of depth of penetration (due to small particle sizes) of nano-based products, ease of application (little training required) and the proven high degree of hydrophobicity (water-repellent characteristics) [14] are ideally suited to cost-effective labour-intensive maintenance actions, exceeding the performance of traditionally used preventative maintenance products. The nanotechnology solutions are also used to present the ability to partially restore roads (especially applicable to secondary, tertiary and urban roads) where the surface integrity has already been compromised, exhibiting continuously increasing surface cracking, disintegration and pothole formation, at a fraction of the costs of partial reconstruction as often required.

2. Applicable Nanotechnology Solutions to Road Maintenance

The applicable use of safe nanotechnology solutions for the labour-intensive maintenance of existing roads is shown in terms of the:

- Protection of and restoring of the surface integrity of existing road surfaces through the application of applicable hydrophobic Nano-Polymer Nano-Silane (NPNS) “clear-seal” nanotechnology solutions, the effect of which is demonstrated (under extreme conditions) on an:
 - Unsurfaced unprotected compacted laterite soil (common weathered material found between the tropics) [16];
 - Unprotected compacted high-quality crushed stone pavement base layer with no prime or any other surfacing;
 - Existing surfaced road with the integrity of the road surface already severely compromised, exhibiting severe crocodile cracking (also known in some parts of the world as alligator cracking).
- Effective repair of roads containing multiple potholes using pre-packed anionic NME repair pothole kits to create a hydrophobic restored road surface, which are easy to use, requiring a minimum of effort and training, and
- The resealing of the road using a hydrophobic anionic NME modified binder slurry seal to restore some deformities in the wheel-tracks and produce a labour-intensive, hydrophobic, cost-effective, water resistant and durable surfacing.

All of these road surface periodic maintenance and restoration actions can easily be performed using labour-intensive operations, requiring minimum training. In light of

high unemployment rates in many parts of the world, there is a heightened need to create employment through infrastructure investments. The introduction of nanotechnology solutions for the effective maintenance and restoration of road networks can result in the creation of rapid employment opportunities with considerable advantages in terms of road asset protection.

3. Fundamental Principles Applicable to the Selection of Nanotechnology Solutions Suitable for Road Surface Maintenance

3.1. General

The understanding of the benefits to be gained and the principles associated with the use of new-age nanotechnologies are crucial to the successful introduction thereof in the roads industry. General concerns in terms of issues such as health and safety obviously need to be addressed. The general adoption of new technologies is closely linked to the ease of application, not requiring complicated procedures (e.g., similar to the successful introduction of new telecom (cellular phones) and IT devices (laptops)).

The same principles will apply to the introduction of new technologies in the roads industry. Of considerable importance in the era following the devastating impact of the COVID-19 pandemic is the ability to provide more employment opportunities without considerable investments in advanced training. These elements could prove critical in the fast-tracking of new nano-technologies in a top-down policy approach, especially if advantages in the use of the new technologies can be shown to be superior in performance compared to traditionally used methods and products (even in a conservative environment such as the roads construction and maintenance industry).

It follows that the basic criteria to ensure that nanotechnology solutions are successfully implemented must be clearly identified and assessed in the line of intended application, i.e., in this case, sustainable and improved road maintenance actions (products together with application methods), resulting in cost-effective road-asset preservation.

The following fundamental basic characteristics associated with available, proven and/or new nanotechnologies will ensure that risks are minimised through the introduction of these technologies in the road maintenance environment [14]:

- Toxicology, health and safety of the use of various nano-scale products;
- Environmental aspects, leaching and affecting ground-water;
- Nanotechnology products such as a binder and/or sealer;
- Stability of the nano-modified stabilising agent in a carrier fluid, e.g., water for dilution and ease of application, suitable for labour-intensive applications;
- Quantity (volume) of the nano-silane to be added, as influenced by the relative surface area or coverage needed to achieve the required characteristics of surface integrity—this aspect could be closely related to the condition of the existing surface that can be worse in the wheel-tracks than outside the wheel-tracks;
- Hydrophobic characteristics as required with the addition of the nano-silane to the nano-polymer for road surface maintenance;
- Compatibility aspects of nano-silanes and nano-polymers to provide a stable product resistant to degeneration;
- Engineering evaluation of the effect of Nano-Silane Nano-Polymer (NPNS) hydrophobic (water-proofing) qualities and the required stability, quick drying and engineering strength criteria of durable NME pothole repair mixes (i.e., compressive strengths, tensile strengths and durability), and
- Cost—aspects associated with the use of new nanotechnology-based products for periodic preventative and restoration maintenance of existing roads.

Every one of these aspects is of importance in the evaluation of new nanotechnology-based products and is discussed in detail in Reference [14]. However, some aspects of high importance to the road industry and labour-intensive applications (with specific reference to toxicology, health and safety) and environmental impact of the use of various nano-scale products are expanded upon in short. Only aspects of importance to road surface

maintenance (complimentary to the above) are illustrated for clarity of understanding of the various concepts.

3.2. Toxicology, Health Safety and Environmental Impact

Many of these NPNS-based products are generally available and used in the built environment and form the basis of numerous Do-It-Yourself (DIY) products generally available and sold to the public. These products include sealants (water-repellent agents that are sprayed onto walls of houses to avoid and prevent water ingress and damage to houses), adhesives and paints, etc., utilising the “excellent mechanical, optical, thermal and electrical properties” of these organofunctional nano-silanes. Generally, these products show typical conditions for safe applications, an example of which is shown in Figure 1. These protective recommendations are usually also applicable to routine road maintenance activities (e.g., grass cutting) and road construction activities using bituminous products.

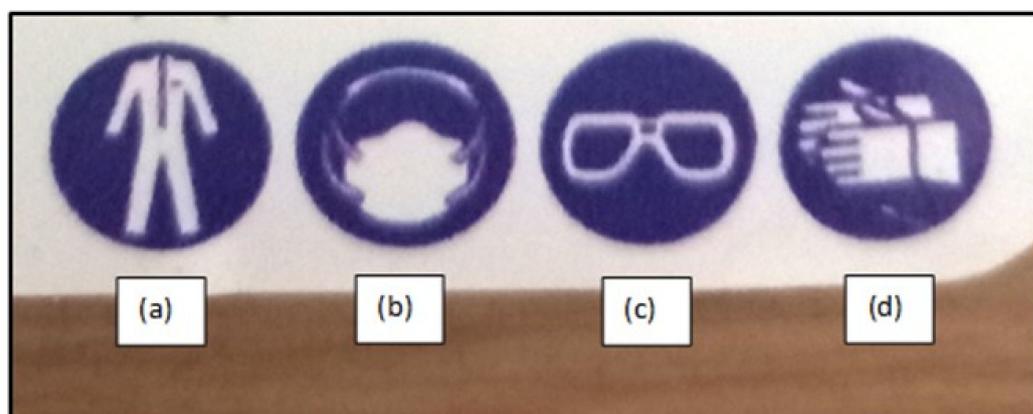

Figure 1. Normal recommendations found in DIY products generally available in hardware stores for the water-proofing of houses; (a) overalls; (b) mask; (c) eye-protection; (d) gloves.

However, these products for the protection of stone buildings originated in Europe [2–4], and good-quality products will meet the health and safety and environmental regulations in-place in the European Union (EU). Many silane couplings, which are freely available commercially, will form siloxane bonds. However, of these, only a few known nano-silanes will have the “correct balance of volatility and reactivity without being harmful to society” or to the materials being treated [4]. Hence, it is of importance to take cognisance of the “Safety Sheets” when selecting an appropriate safe product—similar to the selection of any “safe” house-hold cleaning agent.

Two chemical processes are usually applicable with the addition and use of nano-scale products in the built environment. The first occurs during the mixing thereof with a carrying fluid during any construction/maintenance activity, (referred to as a process of hydrolysis) (e.g., mixing with water), and second, during condensation (when the product attaches to the material during treatment or stabilisation). During any of these two processes, by-products can be formed. It must be ensured that any nano-scale product used does not generate any by-product (liquid or gas) that may be toxic in any way. The by-product formed during the hydrolysis process of the nano-silane when in contact with water is of fundamental importance in the selection of an appropriate and applicable nano-silane to be used in general engineering projects [4]. The most appropriate and designed alkoxy-silanes will form water as a by-product, or at the worst, a non-corrosive alcohol [4].

Alkoxy-silanes (also referred to as organo-functional silanes due to the water-repellent molecule attached to the silicon element), generally available for water-proofing of buildings, have low vapour pressures and do not form toxic gasses or acids during hydrolysis. Similarly, the approved products used for the treatment of buildings/houses, etc. (e.g., DIY products) form water as a by-product during consolidation (attachment onto the surfacing), forming a

three-dimensional matrix covering all exposed surfacings; it has been chemically designed to attach to [15], and it will, for example, not attach to exposed skin, as will be demonstrated.

From an environmental point of view, the alkoxy-silane is bound to the sub-strata through chemical bonds (e.g., Si-O-Si bonds—one of the strongest in nature [15]) (in the case of silicon rich materials—the second most abundant element in the crust of the earth after oxygen). Using naturally available materials containing few or no free silicon elements to affect silicon bonds (e.g., calcretes or severely weathered laterites), an applicable Hydroxy Conversion Treatment (HCT) [15] nano-product should be added to the compatible nano-silane, ensuring that chemical bonds of similar or stronger strengths are achieved [15].

It follows that recommended nano-silane-based products must be scientifically designed to strongly attach chemically to the generic fingerprint of the minerals contained in the materials that are being treated, resulting in no risk of leaching and/or contamination. The alkoxy-silane modification of traditionally used binders, such as bitumen (as contained in, e.g., bitumen emulsions to form anionic NME products), will firmly attach the bitumen to the stone/aggregate/soil, preventing any bitumen from detaching from the soil and causing any contamination. The same principle also applies to the modification of bitumen for use in asphalt manufacturing. The modification of the binder, using a material-compatible nano-silane product (EU compliant), will assist greatly to prevent or at least minimise any possible future leaching and contamination caused by the binder in the asphalt surfacing of roads.

3.3. Particle Size and the Effect on Road Surface Maintenance

The main objective of road periodic (preventative) surface maintenance is to protect and/or restore the integrity of the surfacing to prevent secondary distress. The larger the particle sizes of the products used for road surface maintenance, the less would be the depth of influence on the road surface. This aspect is visually demonstrated in Figure 2.

From Figure 2, it is seen that surface rejuvenators (e.g., diluted bitumen emulsions), comprise particle sizes between 2 and 5 μm (similar to most of the available polymers), will seal some micro-cracking with little in-depth penetration and protection of the surfacing. It follows, that particle sizes of micro dimensions will have a limited impact on restoring the integrity of the road surface. It is well known that the use of rejuvenators as a road surface maintenance action will increase the durability of the road surfacing for a year or two only. In the case of the use of a diluted bitumen emulsion, road markings will be affected and will have to be re-instated as a road-safety measure. In contrast, the use of a clear-seal (diluted NPNS) will show much deeper penetration with a longer-lasting effect.

3.4. Water-Repellent (Hydrophobic Effect) of Nano-Silanes

In terms of road surface maintenance, resistance to water damage is of cardinal importance. Any penetration of water into micro-cracks will, under the action of traffic loading, develop large pore-pressures able to quickly destroy the integrity of the road surfacing. The result is an accelerated deterioration and the development of pumping of fines from the supporting base layer. If not addressed immediately, potholes will develop with severe safety and cost implications. A major advantage of the use of material-compatible nano-silanes is that the surface of the material it attaches to is changed to become hydrophobic and will repel water. This water-repellent nature is demonstrated in Figure 3.

The practical effect of the treatment of a material with a material-compatible nano-silane is shown in Figure 4, with the treatment of black-cotton soil material. The treated material has been broken into small pieces and, although gaps exist between the separate material (treated black-cotton clay) pieces, the water drops do not penetrate the material or gaps and form beading on the top of the nano-silane treated material. The same effect is achieved with the treatment of other materials such as fine-grained sands, where water drops will remain suspended on top of the sand as shown in Figure 4b. In this case, the “glue” in the NPNS, i.e., the nano-polymer, is not present to bind the particles together and create the strength as part of a material-compatible NPNS treatment.

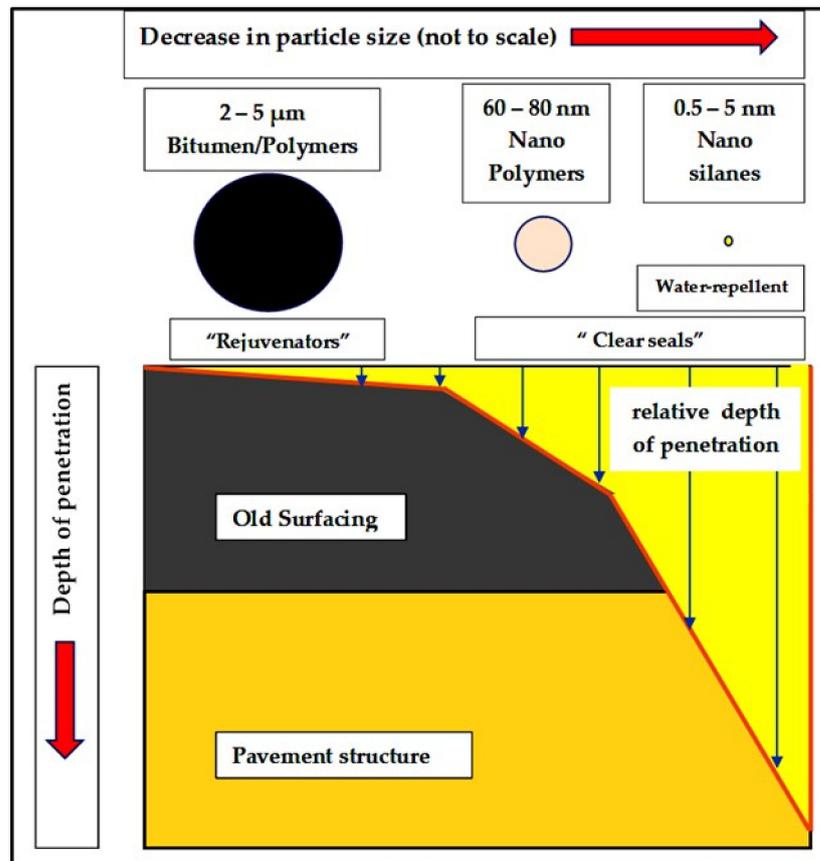

Figure 2. Effective penetration using rejuvenators (diluted bitumen emulsions) in comparison to “clear-seals”, i.e., nano-silanes-modified nano-polymers (NPNS) of different particle sizes for the treatment of old road surfacings (same surface condition).

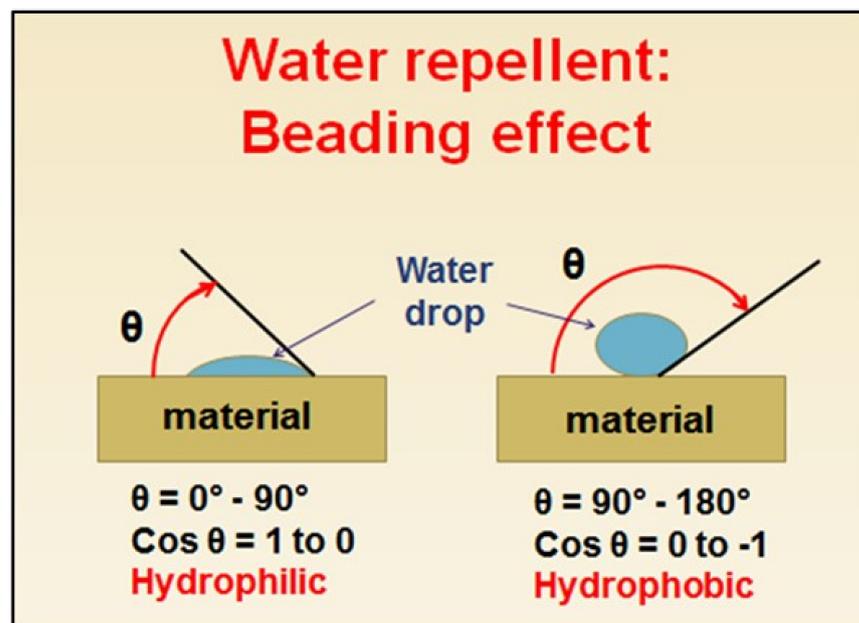

Figure 3. “Beading” of water droplets showing the hydrophobic (water-repellent) nature of a nano-silane-treated surfacing of a material.

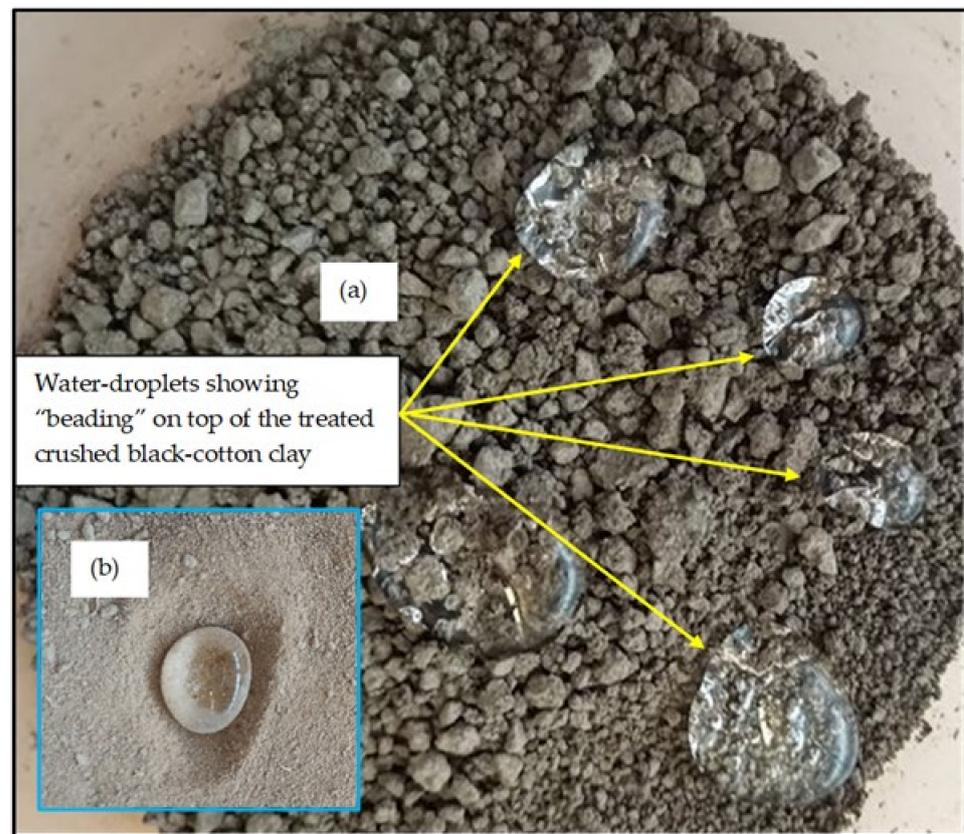

Figure 4. (a) Practical demonstration of the hydrophobic (water-repellent) surfacing created using black-cotton soil treated with a material-compatible nano-silane. The hydrophobic nature of the surface of the broken clay particles prevents the water droplets shown on top of the broken treated clay particles from penetrating the material or the gaps between the broken pieces of the treated clay sample; (b) Similarly, a water drop remains suspended on fine-grained sands treated with a material-compatible nano-silane.

3.5. Ease of Use—Labour-Intensive Friendly Application of NPNS

The NPNS is diluted into water to contain about 5 per cent NPNS as a “clear-seal” to be applied to road surfaces. Application can be performed by water truck (at a uniform rate) but is user friendly for easy application by hand sprayer as demonstrated in Figure 5. Due to the small particles of the clear-seal, the particles penetrate the surface quickly and are dry within a maximum of 30 min as shown on the right, with a Marvil apparatus to measure the rate of water penetration into the surfacing. The clear-seal (GE-NANO clear seal) (NPNS diluted in water (5 per cent concentration)) is normally applied at about 1 to 2 l/m²—the application rate depends on the condition of the road surface and is applied at a rate that will not result in run-off from the road surface. In cases such as that shown in Figure 5b, where the clear-seal is applied as a preventative measure, no water penetration was measured over set time intervals lasting in excess of 3 hours. Clear-seals applied as a preventative measure will require no new road markings and will not result in any pick-up and contamination of vehicles.

The Marvil apparatus is sealed onto the surfacing using putty to prevent the water from seeping out between the surfacing and the bottom of the Marvil apparatus. The fact that the rate of application of the clear-seal should be a function of the condition of the road surface makes application by hand sprayer the preferred method of application. With hand application, the rate of application can be adjusted based on visual observations. With more distress in certain areas of the road surface (e.g., the wheel-tracks), the rate can be controlled to prevent run-off and wastage. Application by water bowser will, in the case of a varying in the surface condition, result in over- or under-application along a length of road.

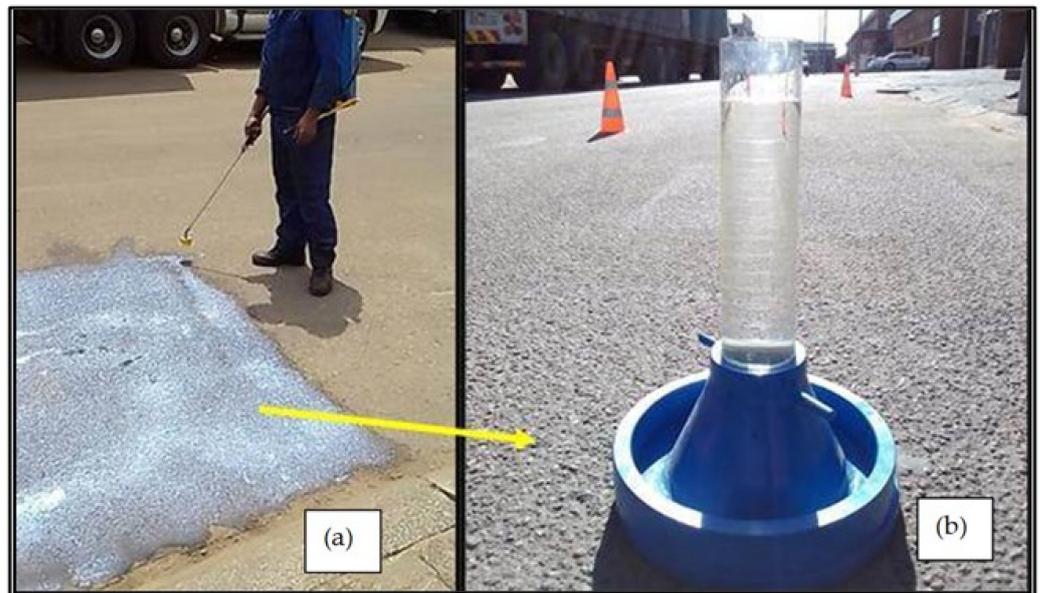

Figure 5. (a) Application of a clear-seal by hand sprayer at a rate of approximately 1 to 2 L/m² (about 5 to 10 mL of NPNS/m² at a material cost of about US\$ 0.10/m² to US\$ 0.20/m²)—note the close proximity of the sprayer head to the road surface to prevent loss during windy conditions; (b) The dried surfacing 30 min after application of the clear-seal with a Marvil apparatus placed on top of the surfacing to measure the rate of water penetration into the treated surface.

The Marvil apparatus was used to measure and quantify the effect of a clear-seal application on various surfacings. Measurements were taken before the clear-seal application, after the clear-seal had dried and at some time after the treated surfacing had been exposed and subjected to traffic loading. Worst-case scenarios were selected to show the water-repellent nature of a clear-seal under the various scenarios. The clear-seal product (GE-NANO clear-seal) (Geonano Technologies (Pty) Ltd., 18 Davies road, Wychwood, Germiston, 1401, South Africa) was applied by hand sprayer (refer Figure 5) to the various surfacings to quantify, in practice, the impact thereof, i.e., to a:

- Poor-quality untreated compacted laterite material;
- Compacted high-quality crushed-stone base layer (without any surfacing or protective prime), and
- Surfaced road with the surfacing (asphalt) exhibiting extensive crocodile cracking (alligator racking), which severely compromised its ability to prevent water-ingress into the base layer of the pavement structure.

4. Nanotechnology Solutions to Road Maintenance: Protecting and/or Restoring the Integrity of Road Surfaces

4.1. Clear-Seal Applications

As discussed, various material surfacings were treated and tested to measure and quantify the impact of the clear-seal application. In all examples, the clear-seal was applied by hand sprayer to saturation of the material as shown in Figure 5, at a rate adjusted by eye to limit (prevent) run-off of the clear-seal and to optimise application rates.

4.1.1. Treatment of a Poor-Quality Material Containing More than 25 Per Cent Kaolinite Clay at the University of Pretoria, Engineering 4 Facility

A small section of this compacted material was treated to test the hydrophobic nature that can be achieved with the GE-NANO clear-seal treatment. The material consisted of a poor quality G10 [18] clay-based material compacted to 93% mod AASHTO [19,20] as shown in Figure 6a. The treated section is shown as an inset in Figure 6a. After drying, water was poured onto the treated surface, the effect of which is shown in Figure 6b.

The beading of the water shows the high degree of hydrophobicity achieved through the treatment of the poor material (compare Figure 3). No water penetration tests were performed on this poor-quality material.

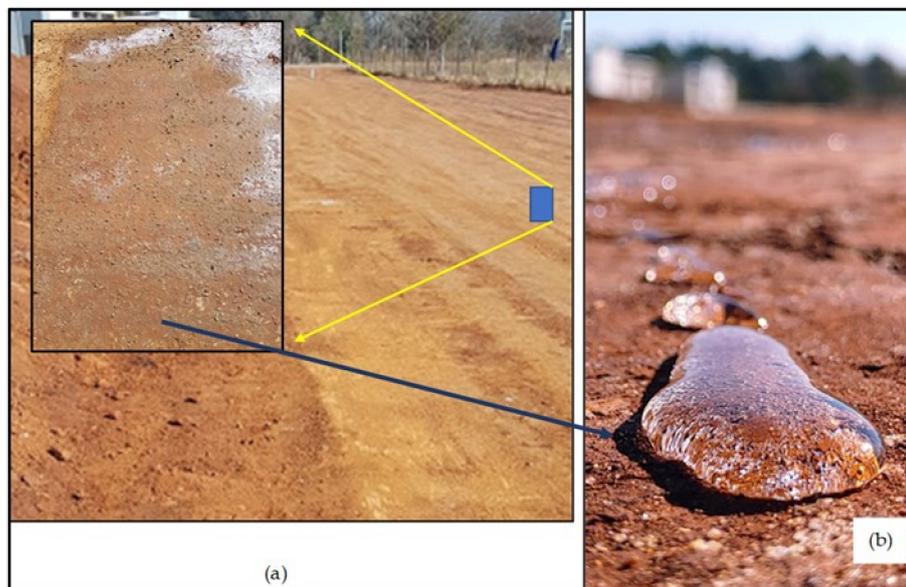

Figure 6. (a) poor-quality clay material (G10 quality material [18]) compacted to 93% mod AASHTO [19,20] and hand-sprayed with a GE-NANO clear-seal until saturation; (b) After drying of the clear-seal, water was poured onto the treated section—the shape of the water drops shows the level of hydrophobicity achieved on the surface of the red-clay material (refer Figure 3).

4.1.2. Treatment of a Good G1 Quality Crushed Stone Base Layer That Has Not Been Primed at the University of Pretoria, Engineering 4 Facility

A section of a newly constructed good G1 quality [18] base layer compacted to 88% of ARD [21] was left untreated without any surfacing or protective prime at the newly constructed Engineering 4 facility at the University of Pretoria. As a “worst case” scenario, the impact of the application of the GE-NANO clear-seal on this untreated granular layer was measured and quantified. The same clear-seal product (as applied on the red-clay material shown in Figure 6), was applied by hand-spray to the exposed base layer at a rate to saturation. The materials cost of the application of the GE-NANO clear-seal was approximately US\$ 0.08/m² to US\$ 0.12/m². Shortly after application of the protective clear-seal, 5 mm of rain fell at the site and the protective impact achieved through the application of the clear-seal product was tested through the turning of a truck over the treated and untreated G1-quality [18] base layer, the visual effect of which is shown in Figure 7.

Nine months after application of the GE-NANO clear-seal, the Marvil apparatus was used on the G1-quality [18] layer to test the rate of penetration of the water into the G1 [18] layer. Tests were performed on an untreated section of the G1 [18] base, on a section of the G1 [18] base that was treated with the clear-seal, but not subjected to any traffic and on a section treated with the clear-seal and subjected to light vehicle traffic over the nine-month period. The conditions of the G1 quality [18] crushed-stone base layer test sections after a period of 9 months are shown in Figure 8. The penetration rates of the G1 layer after being exposed to elements for more than 9 months with some vehicle movement on some sections are summarised in Table 1. The period covered spanned the 2020/21 summer rain-fall season—an unusually good season in terms of the rain recorded. The water damage from the rain on the exposed G1 [18] base layer with no application of the clear-seal can be seen in Figure 8a. The corresponding conditions of the G1 [18] test sections (where the Marvil tests were performed) after cleaning the surfacing from any loose material through light brushing with a hand brush are shown in Figure 9.

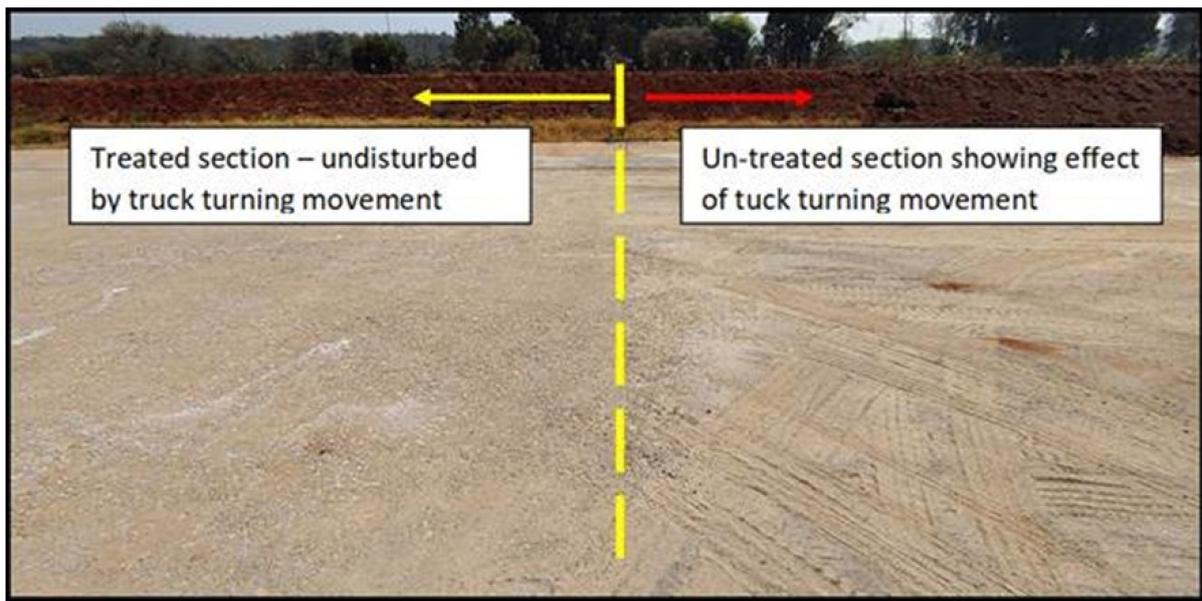

Figure 7. NPNS clear-seal application on an unprotected G1 quality [18] base layer at the Engineering 4 facility at the University of Pretoria, showing the effect of truck turning movements on sections treated with the clear-seal [18] (left) versus untreated section (right)—the application was performed by hand sprayer to saturation.

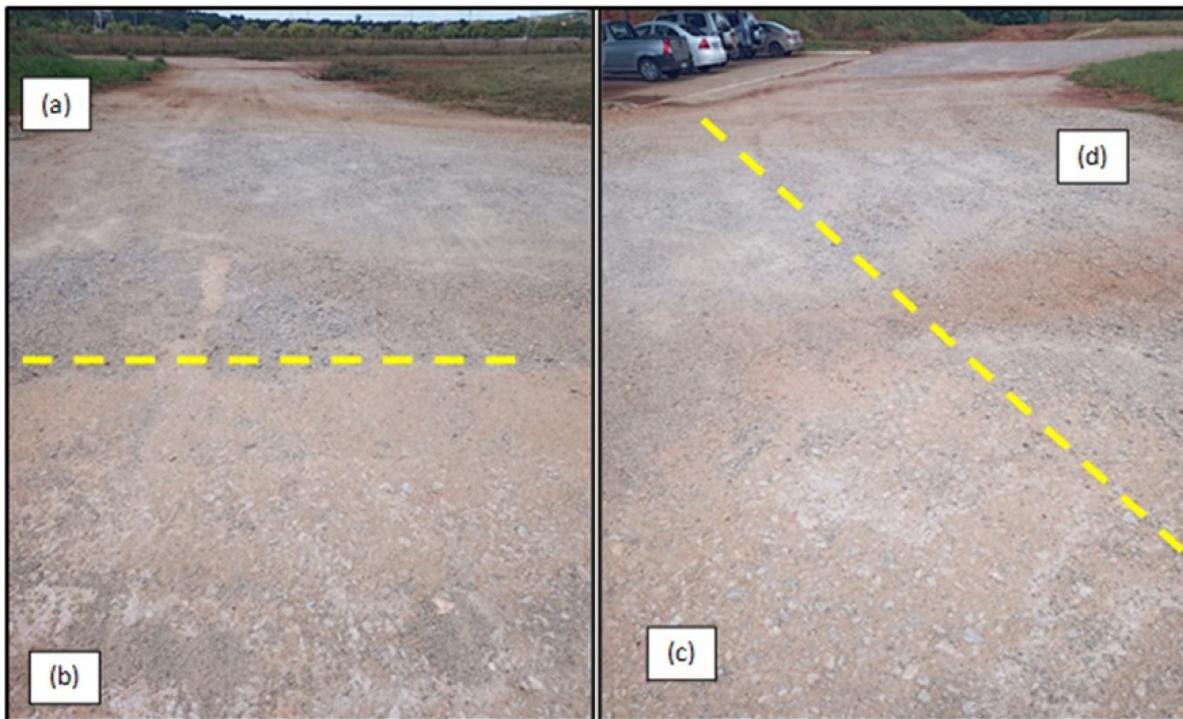

Figure 8. Condition of the G1 quality [18] base layer at the University of Pretoria, Engineering 4 facility after being open for 9 months from 21 August 2020 to 20 May 2021: (a) Untreated G1 layer subjected to rain; (b,c) GE-NANO clear-seal treated G1-layer subjected to rain; (d) Clear-seal treated G1 layer subjected to rain and light traffic.

Table 1. Penetration rates tested using Marvil apparatus of the application of a NPNS GE-NANO clear-seal on an exposed G1 quality [18] base layer at the Engineering 4 facility at the University of Pretoria (date applied—21 August 2020; date tested—20 May 2021)—test duration on each section = 1 h.

Permeability Measured on the G1 Quality [18] Base-Layer per Volume of Water	G1 Quality [18] Base Layer—Untreated (Figure 8a)	G1 [18] Layer—Treated with a NPNS GE-NANO Clear-Seal Applied at $\pm 1 \text{ L/m}^2$ —No Traffic (Figure 8b,c)	G1 [18] Layer—Treated with a NPNS GE-NANO Clear-Seal Applied at $\pm 1 \text{ L/m}^2$ —with 9 Months of Light Vehicle Travelling and Some Surface Damage (Figure 8d)
@ 50 mL	0.370 L/h	0.035 L/h	0.059 L/h
@ 100 mL	0.260 L/h	-	-
@ 150 mL	0.207 L/h	-	-
Permeability at different intervals			
20 mL	-	0.030 L/h	-
25 mL	-	-	0.061 L/h
75 mL	0.279 L/h	-	-
Average Permeability	0.279 L/h	0.030 L/h	0.061 L/h

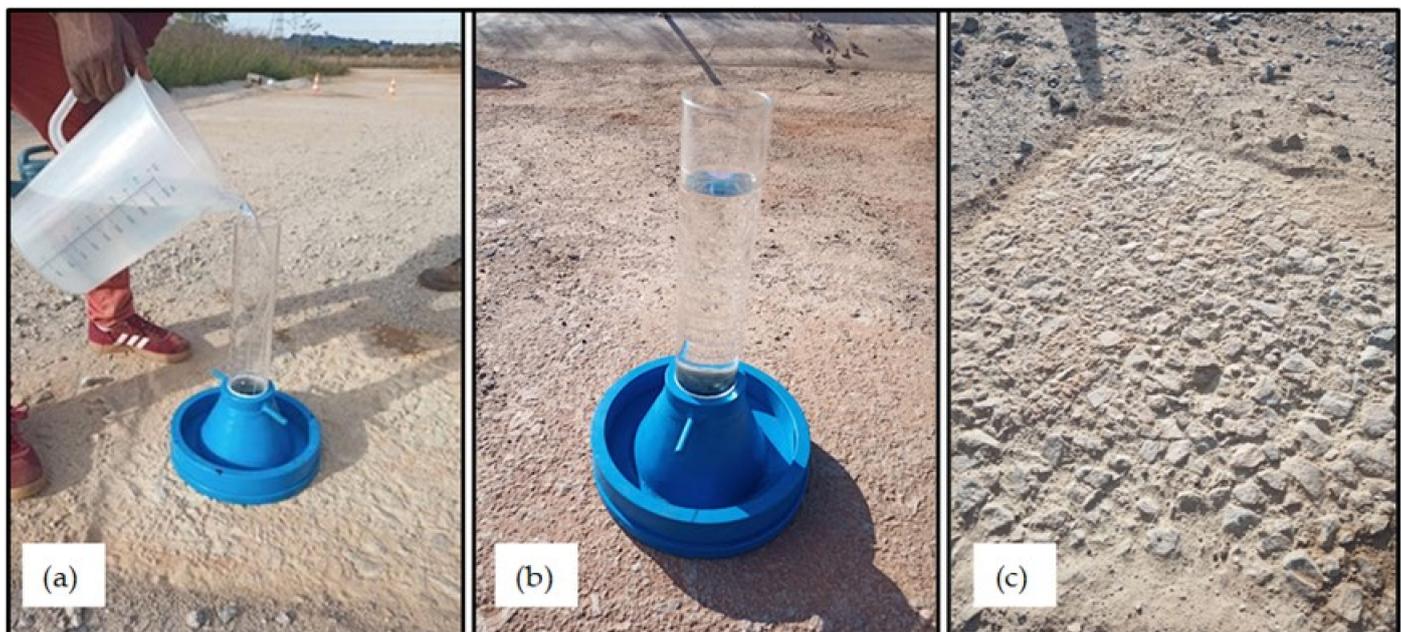

Figure 9. (a) Condition of G1 [18] unprotected surfacing subjected to 9 months of rain in 2020/21 Pretoria, South Africa (loosened material brushed clean); (b) G1 [18] base layer with a GE-NANO clear-seal applied after 9 months of rain in 2020/21 and no traffic; (c) Clearly brushed surfacing of G1 [18] base layer treated with a GE-NANO clear-seal subjected to 9 months of rain and light traffic.

The effect of the GE-NANO clear-seal as measured in Table 1 and the corresponding photographs in Figure 9 are conclusive. The clear-seal application protected the G1 quality [18] crushed stone base layer over a period of 9 months without any surface damage and reduced the water ingress by a factor of 10. Although the surfacing experienced some damage under the action of light traffic over a period of 9 months (Figure 9c), the base layer still retained considerable resistance to water ingress, which is still one-fifth of that of the untreated G1 [18] base layer section. The G1 [18] base layer subjected to light traffic over a period of 9 months illustrates the depth of protection provided by the clear-seal application.

4.1.3. Treatment of Road Section with Some Severe Crocodile Cracking (Alligator Cracking) in the Wheel-Tracks

Similar to the measurements on the G1 quality [18] base layer, the effect of an application on a GE-NANO clear-seal (diluted NPNS) was shown on a severely compromised surfacing exhibiting severe crocodile cracks (alligator cracks). The condition of the surface with the Marvil apparatus is shown in Figure 10a before any treatment. Water is clearly seen seeping out underneath the Marvil apparatus through the extensive network of crocodile cracking (alligator racking). After application of the GE-NANO clear-seal to a rate to saturation and the drying thereof, another Marvil test was performed close to the original test site (refer to comparative test sections clearly visible in Figure 10b). After the clear-seal application no water could be observed in the cracks leaving from the Marvil apparatus.

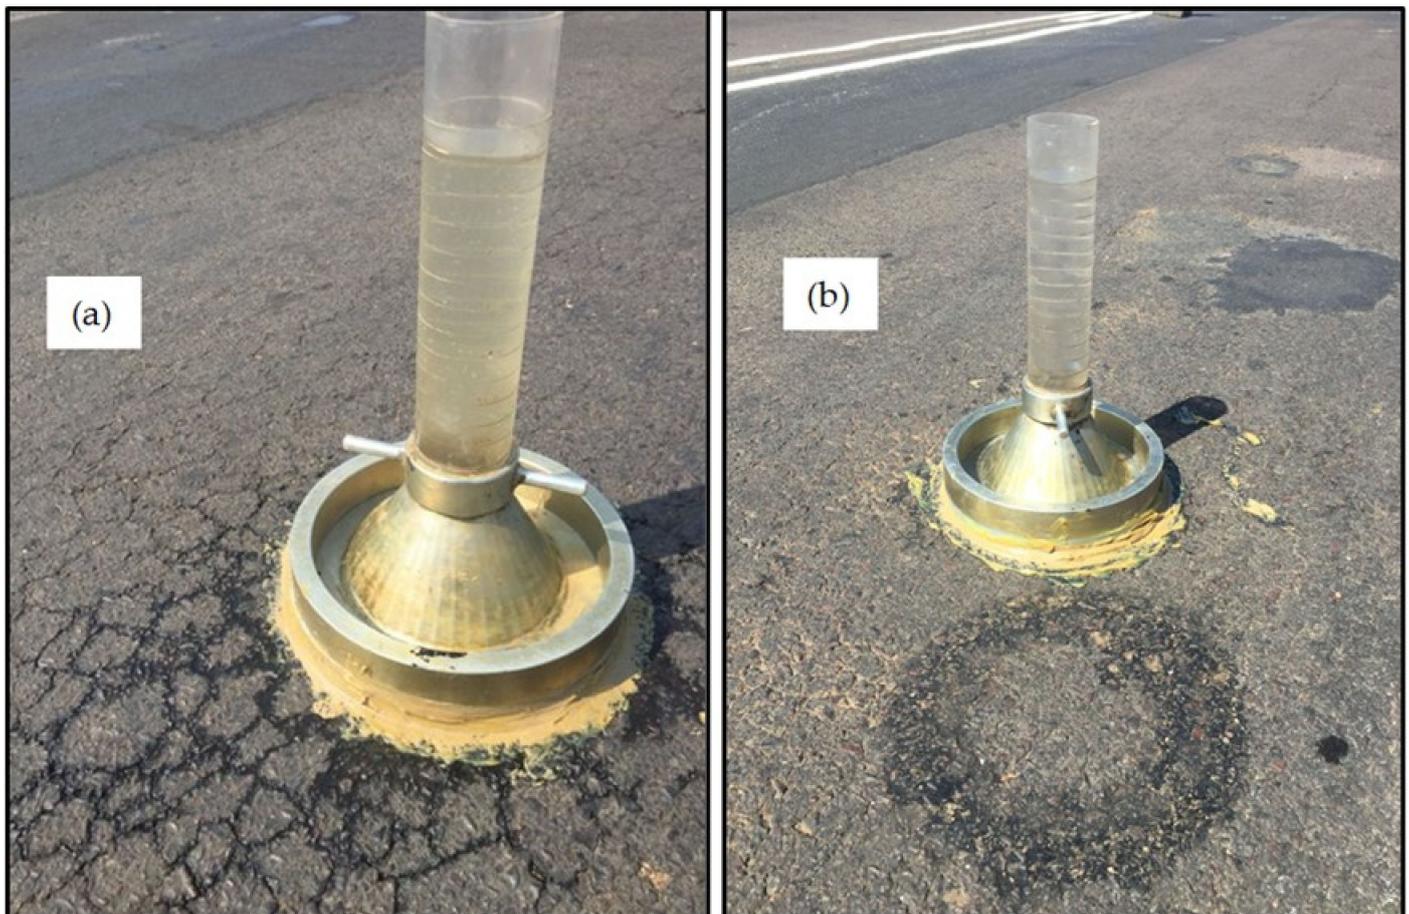

Figure 10. (a) Water penetration before application of a clear-seal, showing water seeping out along the extensive network of cracks; (b) Marvil test after application of a clear-seal showing the sealing effect of the clear-seal.

Water penetration using the Marvil apparatus was measured both before and after the application as recorded at different time intervals, as given in Table 2. Table 2 also contains comparative measurements taken after a period of 14 days, during which time the road was opened to normal traffic. The reduction in water penetration into the severely cracked surface is clearly evident. After application of the clear-seal, the water ingress into the pavement structure was reduced by 97 per cent. After 14 days of the road being opened to traffic, the water ingress was still reduced by 81 per cent. These results are significant, and in combination with a hydrophobic cost-effective slurry mix, could restore the integrity of the surfacing for a number of years.

Table 2. Penetration rates tested using the Marvil apparatus of the application of a clear-seal on a severely cracked surfacing exhibiting closely spaced crocodile cracking (refer to Acknowledgements).

Permeability at Different Intervals	Pre-Treated (Figure 8a)	After Application of a Clear-Seal (Figure 8b)	14 Days after Application of Clear-Seal and Opened to Traffic
7 min	0.214 L/h	0.000 L/h	0.017 L/h
15 min	0.200 L/h	0.008 L/h	0.020 L/h
20 min	0.150 L/h	0.009 L/h	0.018 L/h
Average Permeability	0.188 L/h	0.006 L/h	0.036 L/h

In order to address any concerns about a possible decrease in the skid-resistance of the surfacing caused by the application of the clear-seal, skid resistance testing was performed using the British Pendulum Tester (Figure 11), both before and after the application of the clear-seal. The results of the skid-resistant tests are given in Table 3. No statistical difference between the test performed before and after the application of the clear-seal was measured.

Figure 11. Skid resistance testing performed before and after application of a clear-seal [18] (refer to Acknowledgements).

Table 3. Skid-resistance measurements using the British Pendulum testing device before and after the application of the clear seal (GE-NANO clear seal).

Pendulum Test Results	Control (No Seal)	With Clear-Seal Application
Test Point 1	100	110
Test Point 2	110	100
Test Point 3	110	95
Test Point 4	90	100
Test Point 5	95	90
Total (Average)	101	99

4.2. Repair of Potholes Using Pre-Prepared GE-NANO NME Pothole Repair Kit

In cases where damage in terms of potholes have already occurred, the surfacing can quickly be fixed with an anionic NME gravel mix pothole repair kit (GE-NANO Pothole Repair kit) (Geonano Technologies (Pty) Ltd., 18 Davies road, Wychwood, Germiston, 1401, South Africa) (Figure 12). Due to the organofunctional modification of the anionic NME mix, the pothole mix will dry within an hour. The use of an anionic NME pothole mix (GE-NANO Pothole Repair Kit) is performed at a fraction of the costs of traditional cold mix, providing a hydrophobic (water-repellent) restored surfacing. The tested Unconfined Compressive Strengths (UCS) and the Indirect Tensile Strengths (ITS) performed according to the recommended rapid curing process in a dry and wet state [16] are shown in Table 4. Before the repair of potholes, the hole should first be cleaned of any loose material as per normal procedure. The pothole must be dry, and for potholes requiring more than one bag to fill, the exposed material within the pothole should be treated with the application of a clear-seal (diluted NPNS) or by “painting” the cleaned pothole with some spare anionic NME binder.

Table 4. Unconfined Compressive Strength (UCS) and Indirect Tensile Strength (ITS) tests performed on an NME binder prepared GE-NANO Pothole Repair Kit—evaluated against the criteria used to evaluate the stabilisation of material using a material compatible NME stabilising agent [16].

UCS (MPa)		Material Classification [16]	ITS (kPa)		Material Classification [16]
UCS (dry)	4.4	NME1	ITS (dry)	350	NME1
UCS (wet)	4.3	NME1	ITS (wet)	320	NME1
RCS *	98%	NME1	RTS **	91%	NME1

* RCS, Retained Compressive Strength [16]; ** RTS, Retained Tensile Strength [16].

The formation of potholes is usually an indication of a severely compromised surfacing in terms of its ability to prevent water from entering the pavement structure. It follows, that the fixing of individual potholes will not be a solution to restore the integrity of the surfacing, and potholes will continue to develop along the length and width of the road. In order to restore the integrity of a road surface, the filling of potholes should be performed as one element in a process to repair and restore the integrity of the surfacing and prevent water ingress into the base layer and the continued formation of potholes.

As per the standard in the industry, anionic NME binder pothole kits (GE-NANO Pothole Repair Kit) used in this demonstration and tests are prepared in 25 kg bags for ease of use on site. Due to the low viscosity of the binder, no problems of application at temperatures above freezing is experienced. These anionic NME binder pothole kits can be produced at a cost of about US\$ 3.00/25 kg (including packaging) at an established place of manufacturing.

Figure 12. (a) Cleaning of pothole; (b) filling pothole with a water-resistant anionic NME gravel (GE-NANO Pothole Repair Kit); (c) hot hole filled and partially compacted by hand, and (d) vehicles driving over filled pothole and increased compaction.

The material must be compacted using normal hand compactors, or alternatively, vehicles can be used to effectively compact the material and fill the pothole to the level of

the original surface. The road can be opened to traffic immediately following the filling and compaction of the pothole, as shown in Figure 12d. The anionic NME pothole binders are designed to bind firmly with the exposed granular materials and handling by hand will cause minimum contamination, with little or no bitumen sticking to exposed skin, as demonstrated in Figure 13, which shows a hand (clean from any bitumen sticking to the skin and a little bit of dirt which can be cleaned with ordinary soap and water) that was purposely used to handle some material from the pothole kit to demonstrate the effect of the organofunctional modification of the bitumen emulsion used to prepare the pothole kits (as discussed in Section 3.1).

Figure 13. Demonstration of the effect of the organofunctional modification of the anionic bitumen emulsion used in the NME gravel pothole kits (GE-NANO Pothole Repair Kt) that is designed to adhere to granular material, resulting in minimum contamination when in contact with bare skin. No bitumen is sticking to the hand, and the dirt can easily be washed using normal soap and water.

4.3. Resurfacing Using a Labour-Intensive Slurry Seal Prepared Using a Hydrophobic Anionic NME Binder

It is unfortunately the experience that numerous roads in various municipalities and regions all over the world have deteriorated due to a lack of maintenance to a condition requiring at least some improvement within the wheel-tracks. A cracked surface, similar to that shown in Figure 10a, is at a point where severe pumping of fines under the action of water and traffic will develop, with associated increase in deformation, reduced riding quality and the development of potholes. In the presence of extensive existing crocodile cracking (alligator racking) and/or pothole filling, the application of a clear-seal (diluted NPNS) and anionic NME binder pothole filling should be followed by the application of a labour-intensive anionic medium NME slurry. Such a reseal can provide some restoration of riding quality, providing a hydrophobic, maintenance-free, flexible, ultra-violet (UV)-resistant new surfacing with an expected surfacing life in the order of at least 5 to 10 years (or longer), depending on traffic and climatic conditions.

Slurry resealing using anionic NME binders can be performed fully through labour-intensive methods as shown in Figure 14. The anionic NME slurry mix can be prepared at a central plant in close proximity to the site in a large concrete mixer and delivered to the site

as shown in Figure 15. Alternatively, the anionic NME slurry can be prepared using labour-intensive methods, with small concrete mixers next to the road, as shown in Figure 16, for application, shown in Figures 14 and 17. Figure 17 also shows the labour-intensive application of an anionic NME slurry mix to a single seal to construct an anionic-modified binder Cape seal [12]. In all cases, final spreading and completion of the anionic NME slurry is performed by hand using squeegees for dissipating the slurry and a drag hessian-mat for final texture. In cases where some substantial repairs are required in the wheel-tracks, the final seal can be preceded by rut-depth deformation filling as shown in Figure 18.

Figure 14. (a) Application of a labour-intensive anionic NME slurry seal to effectively provide a water-repellent new surfacing, preventing water ingress into the pavement structure on a severely cracked surfacing without disturbing the existing surfacing and restoring some riding quality; (b) A hessian drag-net is pulled over the slurry seal to provide an even distribution and even texture to the slurry seal. The anionic NME-modified binder slurry seal is mixed to provide a six-hour working envelope, found to be practical on actual projects, while creating a permanent bonding to the old surfacing and a water-resistant surfacing.

Figure 15. Slurry NME mix supplied to site using a large concrete mixer—spread using hand operated squeegees and obtaining the required texture with a hessian-mat dragged by hand.

Figure 16. Labour-intensive road-side manufacturing of the slurry mix for an anionic NME binder slurry seal or for a modified Cape seal using an anionic NME binder.

Figure 17. Labour-intensive construction of a modified Cape seal using an anionic NME binder slurry mixed on site next to the road.

Figure 18. Filling of deformed areas on the road surface using a medium NME slurry mix as a pre-treatment to address severe deformation before applying an anionic NME slurry across the whole width of the lane and road as shown in Figures 14 and 15.

With little layout, numerous employment opportunities can be created which will provide effective protection to existing surfaced roads from the detrimental effect of water ingress and the resultant formation of potholes. These activities can effectively contribute to the protection of existing surfaced roads and positively address some of the well-documented existing back logs in the maintenance of surfaced road networks.

5. Recommendation for the Labour-Intensive Restoration of Compromised Existing Road Surfacing

The preceding sections demonstrate the labour-intensive preventative and surface restoration practice that can be implemented immediately by road authorities using applicable and proven nanotechnology solutions with enhanced performance characteristics on existing surfaced road networks. In the absence of well-managed MMSs, road networks all over the world have deteriorated to a state where preventative maintenance is no longer a viable option on its own. Many roads have deteriorated to a stage where potholes are a common phenomenon, requiring a combination of the actions as discussed to restore the integrity of the pavement surfacing in a cost-effective alternative to partial reconstruction.

A combination of the labour-intensive options may be viable to safeguard and restore numerous roads, while presenting opportunities for rapid employment as a relief to social problems experienced all over the world. In order to restore the integrity of damaged roads, the process as illustrated in Figure 19 is recommended, following the instructions:

- Step 1: Restore the hydrophobicity of the road surface through the application of an anionic clear-seal (diluted NPNS) by hand application to a point of saturation;
- Step 2: Clean and repair existing potholes using an anionic NME Pothole kit to provide a hydrophobic fill;

- Step 3: Fill all cracked areas and restore some localised deformation by applying an anionic NME slurry mix before restoring the surfacing with an anionic NME slurry mix.

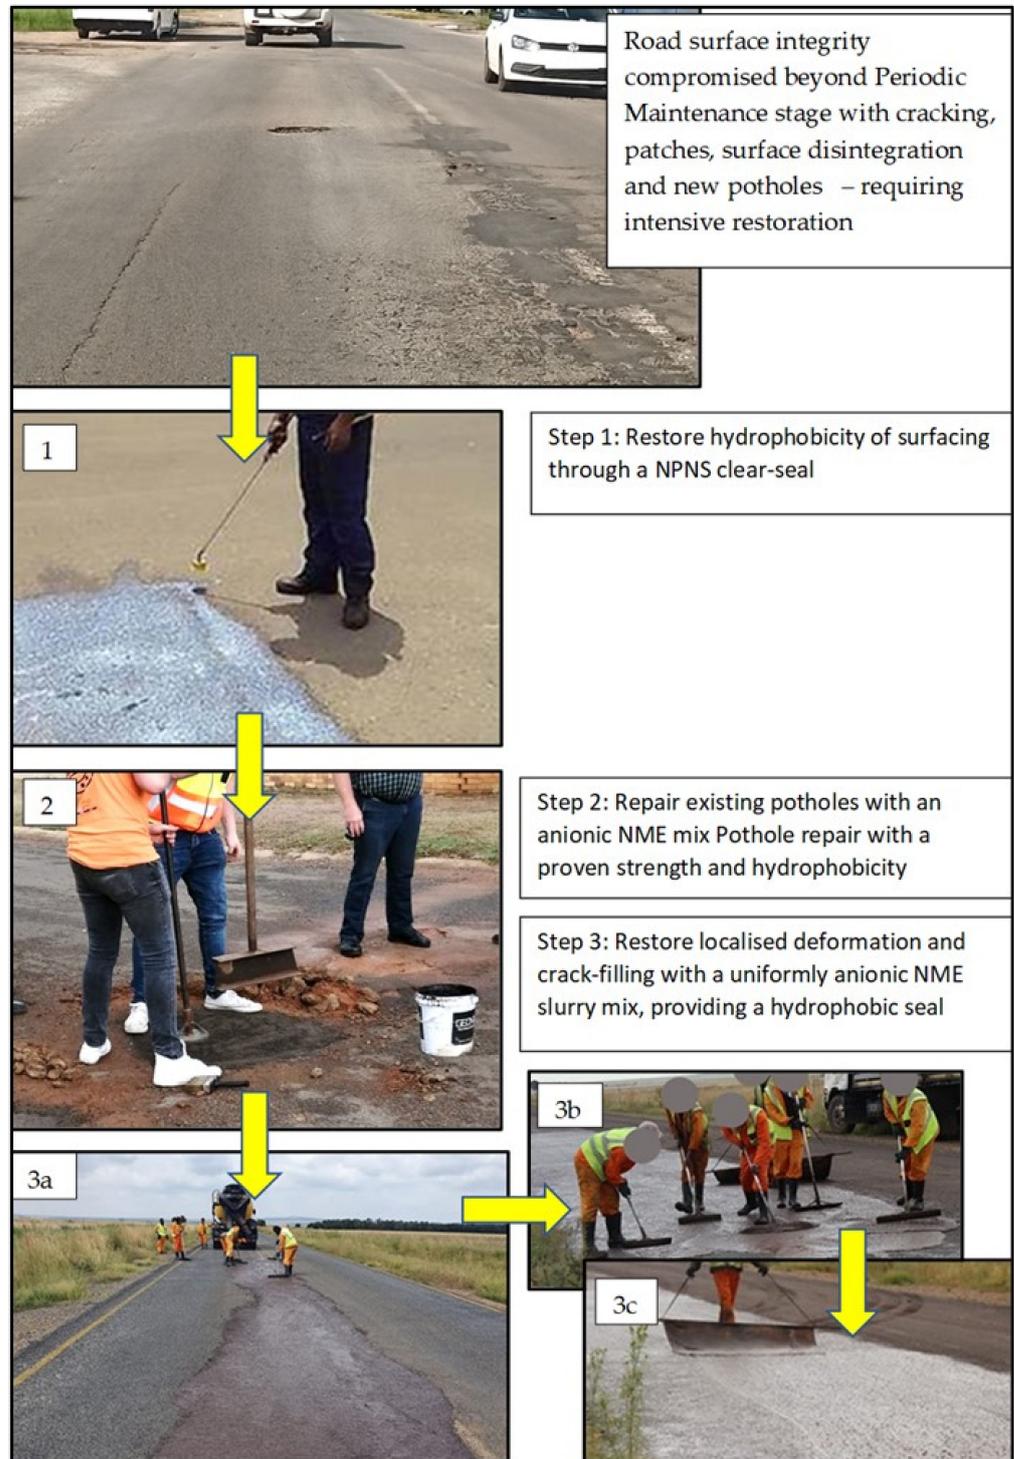

Figure 19. Recommended restoration of compromised road surfacings using available proven nanotechnology solutions suitable for labour-intensive application for rapid job creation providing valuable asset protection.

The long-term effects of the recommended maintenance actions will, inter alia, depend on the:

- Condition of the pavement surfacings and the extent of damage already caused to the pavement layers below the surfacing to which the maintenance actions are applied;
- Traffic loading on the roads;
- Climatic influences.

In order to determine the cost effectiveness of these recommendations, it is recommended that a number of treated sections be monitored on an on-going basis. However, a full economic evaluation will have to include peripheral benefits such as poverty alleviation, accessibility, road user costs, etc. into account. Any such evaluation should be compared to existing actions where, at best, potholes are being repaired on an ad hoc basis or not at all in many countries.

6. Conclusions

Unemployment statistics are at record levels, following the severe economic impact of lockdown all over the world as a result of the pandemic. Governments, especially in developing regions of the world, are under increasing pressure by the electorate to provide employment opportunities and conditions favourable to economic growth. Infrastructure spending is seen as a major instrument available to governments, with an emphasis on high labour content. Good transportation networks are crucial to economic growth and road authorities are under immense pressure to create more employment opportunities through road infrastructure development projects. However, specifications for primary roads in support of economic growth require a high degree of mechanised equipment with little additional opportunities for labour-enhanced work.

However, many of the surfaced road networks in the developing world are lacking preventative maintenance, essential for the protection of the integrity of the surfacing of roads to preserve the structure below the surfacing. Consequently, numerous premature failures are too often the reality, rather than the exception, all over the world. The lack of preventative maintenance and the deterioration of existing surfaced roads present road authorities with unique opportunities to create rapid employment and effective asset protection, utilising the enhanced water-repellent properties offered by available proven nanotechnology solutions. These solutions have been used in the built environment for the protection of buildings since the 1800s and are as applicable to road infrastructure projects.

The same technologies developed for the protection of building houses can also be utilised to protect and repair roads. The unique characteristics of these nanotechnology solutions can provide enhanced resistance against the damaging effects of water—the main, well-documented cause of premature distress on roads. These nanotechnology solutions not only provide improved protection to road surfacings but are also ideally suited for labour-intensive applications. This article has measured and quantified the effect of the application of nano-polymer nano-silane (NSNP) clear-seals under challenging situations on unsurfaced compacted materials as well as severely cracked road surfaces. An immediate effect of a more than 10 times reduction in water penetration was measured under these conditions. There is little doubt that the water-repellent effect of nano-silanes can be beneficiary to road maintenance activities. In combination with pothole kits, providing hydrophobic repairs to existing failures and nano-silane-modified binders for slurry seals, road authorities can contribute not only to rapid employment opportunities, but at the same time, can address asset protection in support of sustainable economic development.

It follows that the applicable and proven nanotechnologies can effectively play a considerable role in the protection of the existing surface road infrastructure due to the inherent properties of the organofunctional silanes in terms of, e.g.:

- Water-repellent (hydrophobic) characteristics that will render surfacings to repel water and prevent the ingress thereof;
- Nano-scale particle sizes that enable deep penetration into the existing surfacing and restore the water-resistant characteristics of existing surfacings;
- Adhesive and strength properties that can contribute considerably to the restoration of surfacings already requiring pothole repairs;

- Applications suitable to be applied at ambient temperatures above freezing without application of pre-heating.

The application of maintenance activities incorporating suitable nanotechnology solutions can be highly effective towards labour-intensive operations. These actions could include the manufacturing and hand application of the following actions:

- Application of a deep-penetrating clear-seal (diluted NPNS) to restore the hydrophobic integrity of road surfacings. The rate of application depends on the condition of the surfacing and hence is best observed and applied by a hand sprayer to prevent over- or under-application. Tests performed on granular materials (as a worst-case scenario) have shown a 90 per cent (or more) reduction in water ingress in a severely cracked surfacing;
- Repair of existing potholes using preprepared pothole kits using an anionic NME binder (with a shelf life of approximately 4 months), providing hydrophobic high strength protection, which, in combination with a clear-seal and hydrophobic reseal, will give extended distress-free protection to the under-laying pavement layers;
- Application on an NME-modified binder medium slurry seal. These seals can be used to restore some existing uneven deformation caused by extensive cracking within wheel-tracks without removing the existing cracked areas, before applying a final NME slurry mix across the whole width of the road. The NME-modified binder will provide a hydrophobic surfacing not achieved using traditional products.

The implementation of these maintenance activities can be performed with little training, requiring no sophisticated equipment and incorporating the water-resistant characteristics of the organofunctional silanes. These actions can all be applied at ambient temperatures, requiring no extensive dangerous heating processes and creating numerous employment opportunities, while protecting one of the most precious existing assets (transport infrastructure) of a country.

Author Contributions: G.J.J., under the directive of the Head of Department of Civil Engineering, W.J.v.S., has led the research into the provision of affordable road infrastructure at the faculty of Engineering, University of Pretoria. He has been instrumental in the design, implementation, and construction supervision of roads using nanotechnologies. W.J.v.S. recognized the potential of nanotechnology solution in the field of pavement engineering more than a decade ago. G.J.J., through involvement in the private sector, has been responsible for the development of scientific principles, ensuring that implementation can be achieved at a minimum risk. All authors have read and agreed to the published version of the manuscript.
