ARTICLE INFO

Keywords: Diethylamine Solid-state sensor $MnO₂@ZIF-8$ Carbon soot ZIF-8

ABSTRACT

Diethylamine vapor is harmful to people if inhaled or swallowed, as it results in the oxidation of hemoglobin in the body into unwanted methemoglobin, which is unable to transport oxygen in the blood, resulting in reduced blood oxygenation. Lack of blood oxygenation leads to hypoxemia. MnO₂ nanorods, carbon soot, and MnO2@ZIF-8 are sensing materials used to prepare solid-state gas sensors that operate at room temperature. The prepared sensing materials were characterized by scanning electron microscopy, transmission electron microscopy, powder X-ray diffraction, X-ray photoelectron spectroscopy, and Fourier-transform infrared spectroscopy. The performance of the MnO₂@ZIF-8 based sensor improved significantly when the carbon soot was introduced into the composite. The effect of the amount of CNPs in the composite on the performance of the sensors was studied. The MnO₂@ZIF-8/CNPs-based sensor with a 3:1 mass ratio was highly selective towards diethylamine vapor over acetone, methanol, ethanol, and 3-pentanone vapors. An *in situ* FTIR coupled with LCR meter was used to understand the sensing mechanism of diethylamine vapor and it was found that the sensing mechanism was by deep oxidation of diethylamine to CO₂, H₂O, and other molecules. The sensing mechanism was studied by monitored by CO₂ band intensity which was produced from the reaction between the sensing materials and the analyte vapor. As the sensor's exposure time increased the intensity of the $CO₂$ IR band increased. We observed the direct relationship between the surface reaction rate and the sensor's sensitivity.

Introduction

Volatile organic compounds (VOCs) are organic compounds that are easily vaporized at room temperature, even at low concentrations [\[1\]](#page-12-0). Highly volatile VOCs, including basic alcohols, amines, ketones, and aldehydes, often have low molecular weights, boiling points, and high vapor pressures [\[2\]](#page-12-0). Diethylamine is an amine compound with a molar mass of 73.14 g/mol and a boiling point of approximately 55 ◦C. It is a volatile organic compound (VOC) that is widely used in pesticides, dyes, pharmaceuticals, corrosion inhibitors, and herbicides. Exposure to diethylamine may cause serious damage to the human skin, eyes, and respiratory systems $[3,4]$. The inhalation of amines is also reported to oxidize hemoglobin from the body system into unwanted methemoglobin, which can distribute oxygen throughout the body; however,

methemoglobin cannot [\[5\].](#page-12-0) Accidental leakage of diethylamine in working environments may result in human health discomfort. However, there are very few scientific articles on diethylamine vapor detection, highlighting the need for a device to monitor diethylamine vapor within the atmospheric working area. A wide range of semi-conductor metal oxides (SMOs), including tin oxide (SnO₂) [\[6\],](#page-12-0) titanium dioxide (TiO₂) [\[7\],](#page-12-0) zinc oxide (ZnO) [\[8\],](#page-12-0) tungsten trioxide (WO₃) [\[9\]](#page-13-0), and manganese dioxide ($MnO₂$) [\[10\],](#page-13-0) have received significant attention from researchers and engineers for application in chemiresistive gas sensors owing to their low cost, ease of synthesis, good stability, good sensitivity, and large surface-to-volume ratio. $MnO₂$ is a transition-based metal oxide that possesses wide morphological flexibility and exists in many crystallographic polymorphs, including α -, β -, χ -, δ -, and ε-polymorphs [10–[12\].](#page-13-0) Owing to their relative abundance and free toxicity,

they are used in many applications, including water treatment, catalysis, energy storage, and gas sensors $[12]$. The synthesis of MnO₂ has received considerable attention owing to its controllable dimensions, morphology, pore size, and surface-to-volume ratio. $MnO₂$ nanostructures, including nanosheets, nanorods, nanoparticles, nanotubes, nanospheres, and nanowires, have been reported to exhibit activity in catalysis and sensing applications $[13]$. Although there are many $MnO₂$ nanostructures, recent reports by Okechukwu et al. have shown that the MnO2 nanorods have high sensitivity toward the detection VOCs [\[14\]](#page-13-0). There are major drawbacks to SMOs gas sensors, which have poor selectivity towards the gas of interest, and they operate at relatively high temperatures above 150 °C [13-[15\].](#page-13-0) Applying high temperatures to the sensor film leads to structural instability, resulting in a poor sensor lifespan. Introducing carbon materials into $MnO₂$ nanostructures improves the electrical conductivity and surface-to-volume ratio, leading to fast response-recovery times and gas sensitivity [\[14\]](#page-13-0). Inexpensive carbon nanoparticles (CNPs) from candle soot are promising materials for application in gas sensors because of their good surface-to-volume ratio, good electrical conductivity, nanosize, high sensitivity, and fast response-recovery times. The source of CNPs soot is the burning of household candle soot in the presence of atmospheric molecules [\[16,17\].](#page-13-0) The sensitivity and selectivity towards detecting the targeted gas from pure SMOs, carbon materials, and SMO-based gas sensors can be improved by introducing zeolitic imidazolate frameworks (ZIFs) owing to their porosity tunability [\[18\].](#page-13-0)

ZIFs are a subclass of metal–organic frameworks with tetrahedral arrangements made up of metal cations and imidazole as an organic linker, with a geometry such as ZIF-8 consisting of zinc ions and 2-methylimidazole. ZIF-8 have small pore apertures (3.4 Å) and large cavities (11.6 Å) and are reported to be hydrophobic, and possess good chemical and thermal stabilities [\[19,20\].](#page-13-0) ZIFs, such as ZIF-8, are mostly used in gas storage, separation, sensing, and purification of small molecules because of their tunable pore sizes [\[21\].](#page-13-0) Although ZIF-8 possesses unique properties for gas sensors, to date, there have been only a few reports on ZIF-8 gas sensors because of their poor electrical conductivity; thus, they operate at temperatures between 180 and 400 ◦C, have poor regeneration ability, and there is no evidence of oxidation of the analytes on pure ZIFs sensors $[18-21]$. Because MnO₂ only provide sensing interactions at relatively high temperatures due to their poor electrical conductivity, introducing good conducting CNPs soot on MnO2@ZIF-8 improves the electrical conductivity, resulting in the sensors working at relatively low temperatures. We propose using a ternary composite of $MnO₂$, ZIF-8, and CNPs to detect diethylamine at room temperature (approximately 25 ◦C. Detecting diethylamine using MnO2@ZIF8/CNPs sensors would be energy efficient, highly selective towards diethylamine, durable, and block moisture interference (humidity).

Experimental section

Synthesis of MnO2 nanorods

The MnO2 NRs were synthesized using the hydrothermal method reported by J. Zhang et al. Firstly, 0.63 g of KnMO₄ and 0.25 g MnSO₄ were dissolved in 40 mL of deionized water. The resulting solution was stirred for 30 min to obtain a homogeneous purple solution. The solution was transferred into a 100 mL Teflon-lined stainless steel autoclave, and the hydrothermal process was carried out at 160 ◦C for 12 h. After the reaction, the autoclave was allowed to cool to room temperature. The dark brown precipitate was washed several times with deionized water and ethanol by centrifugation and dried at 80 ◦C [\[22\]](#page-13-0).

Synthesis of MnO2@ZIF-8

Typically, 0.10 g MnO₂ NRs, 0.20 g Zn(NO₃)(H₂O)₆ and 0.80 g 2methylimidazole were dissolved in 40 mL of methanol [\[23\]](#page-13-0). The mixture was constantly stirred for 2 h at room temperature, and the precipitate was collected via centrifugation. The dark brown precipitate obtained was washed several times with ethanol and dried at 60 $^{\circ}\mathrm{C}$ for 12 h.

Prepared of CNPs

The preparation of carbon nanoparticles (CNPs) was done following the reported method by Malepe L et al. [\[17\]](#page-13-0). The pyrolysis of light candles prepared the CNPs, and a ceramic crucible was placed approximately 1 cm above the burning candle to collect soot. After sufficient accumulation of carbon soot, a spatula was used to scrape the product, which was then stored in a vial until further use.

MnO2@ZIF-8/CNPs composite

MnO2@ZIF-8 and the CNPs were added together to form a MnO2@ZIF-8/CNPs composite via physical mixing. 0.6 g of MnO2@ZIF-8 and 0.3 g of CNPs were dissolved in 20 mL of N, N-dimethylformamide. The mixture was sonicated for 15 min and the homogeneous mixture was magnetically stirred at room temperature for 12 h. Subsequently, the product was dried at 80 $°C$ for 12 h ([Fig. 1\)](#page-2-0).

Gold-plated-interdigitated electrode and sensor

The sensor was prepared by drop-coating the prepared material onto a gold-plate interdigitated electrode. The electrode was designed to have 0.1 mm width spacing between the gold lines and was counted to be 18 pairs of 7.9 mm long (see supporting document Fig. S1). The electrodes were washed with ethanol and dried at room temperature before use.

Gas-sensing setup and sensor testing

The electrical characterization of the fabricated sensor investigations was performed using a Keysight E4980A LCR meter connected to the fabricated sensor and the computer via electrical wires, as presented in [Fig. 2](#page-2-0). A voltage of 0.5 alternating current was supplied to the prepared sensor at an optimal relative frequency of 25 KHz [\[24\]](#page-13-0), and the LRC meter, diaphragm vacuum pump, and computer were all connected to a 230 V power source. The sensor was placed inside a sealed 20 L roundbottom flask connected to a vacuum pump to remove the exposed gas and reform oxygen adsorbates by allowing atmospheric air to come into contact with the sensor. $MnO₂$ nanorods, ZIF-8, and CNPs are the sensing materials used to fabricate sensors to detect diethylamine. The prepared and tested sensors include sensor 1 (CNPs), sensor 2 ($MnO₂$), sensor 3 $(MnO₂@ZIF-8)$, sensor 4 $(MnO₂@ZIF-8/CNPs$ with a mass ratio 1:1), sensor 5 ($MnO₂(QZIF-8/CNPs$ with mass ratio was mass ratio 2:1) and sensor 6 ($MnO₂@ZIF-8/CNPs$ with a mass ratio 3:1). As the sensing materials, $MnO₂(QZIF-8)$ was taken as a primary composite, and $MnO₂(QZIF-8/CNPs$ was taken as secondary composite. Sensor 4, sensor 5, and sensor 6 were prepared by varying the mass of the primary composite (MnO2@ZIF-8) in the secondary composite, whereby CNPs were kept constant. Other sensors tested from our laboratory to support our experiments include MnO2/CNPs, all at a mass ratio of 1:1. The mass ratio of the MnO2@ZIF-8/CNPs was varied from 10 to 20 and 30 mg in the preparation of sensors 4, 5, and 6, respectively. All sensors with a 1:1 mass ratio were prepared by mixing 10 mg and 10 mg of their respective materials and dissolving them in 10 mL of DMF. The mixtures were stirred overnight and 10 μL was drop-coated onto the interdigitated gold electrodes.

The prepared sensors were allowed to dry in atmospheric air and subsequently placed in a vacuum desiccator for two weeks to remove any remaining DMF from the sensors. All prepared sensors were tested on five analytes: methanol, ethanol, acetone, 3-pentanone, and diethylamine vapor. One analyte was tested at a time, wherein volumes (1, 2, 3, 4, and 5 μL) were injected into a 20 L round bottom flask at a time. The

Fig. 1. Schematic illustration of the preparation of candle soot (CNPs) and MnO2@ZIF-8/CNPs.

Fig. 2. Gas sensing setup.

contact between the injected analyte and the prepared sensor was 10 min, and the vapor was removed using a vacuum pump that ran at atmospheric pressure by sucking air into the volume chamber (20 L round bottom flask). Subsequently, the sensor was allowed to rest for 3 min before injection. The concentrations of the injected analytes were calculated using the following formula:

$$
C = \frac{22.4 \, pTV_s}{273 \, M_r V} \times 1000,
$$

Where C represents the vapor concentration, *p* and Mr represent the density and the molecular mass of the analytes, respectively. V_s is the volume injected, and V is the volume of the chamber [\[25\].](#page-13-0)

Sensor response and recovery tests

The response time is the time taken by the sensor to reach the plateau of the maximum response. The time taken by the sensor to return to its baseline during analyte vapor removal from contact with the sensor is referred to as recovery time. In this study, the response time was recorded as 90% of the maximum response when the analyte was in contact with the sensor, and the recovery time was measured as 90% before the sensor reached its baseline. The electrical responses of the prepared sensors to the target gas were reported as the relative resistance $(ΔR)$ and defined as

$$
\Delta R = R_{\rm gas} - R_{\rm air} \tag{1}
$$

Selectivity test

Firstly, one mL of each of the five analytes (diethylamine, methanol, ethanol, 3-pentanone, and acetone) was mixed to make five mL. From the mixture, 5 µL of aliquot were tested to investigate the selectivity of diethylamine using the setup shown in Fig. 2.

In Situ FTIR coupled with LCR meter setup and testing

The prepared sensor was placed on the upper wall of a cylindrical glass cell with a volume of approximately 110 mL and closed on both ends using KBr windows. The sensor is electrically connected to an LCR meter [\(Fig. 3](#page-3-0)). The cell was placed at the center of the FTIR sample compartment, wherein the IR beam passed through KBr windows that closed the cell. Before the gas analyte was injected into the gas cell, the sensor was run for about 180 min, a pre-injection period. During the In Situ measurement, approximately 20 ppm of diethylamine vapor was introduced into a cylindrical cell. The LCR meter measured the sensor's electrical response (resistance), and the FTIR spectra were collected every 2 min.

Fig. 3. Schematic illustration of in-situ FTIR coupled with an LCR meter to study the sensing mechanism.

Curve fitting for the infrared CO2 band

The area under the curve was obtained using magic plot software on a selected region of the CO₂ band bending at 673–660 cm⁻¹ on the IR bands. The area was obtained using a Gaussian function for the 6 spectra of the sensors.

Characterization techniques

Samples were analyzed on a JEOL-TEM 2010 (Japan) highresolution transmission electron microscope (HR-TEM) at an acceleration voltage of 200 kV using the Gatan software. TEM sample preparation, the sample was dispersed in ethanol and DMF (1:3), wherein the mixture was drop coated on Holey carbon-coated copper grids. The Holey carbon-coated copper was allowed to dry with the sample before use. Scanning electron microscopy (SEM) was performed at 30 kV using a FEI Nova Nanolab 600 FEG-SEM. SEM pin mounts specimen were used to spray our samples on it, and further carbon coated them before analysed. Structural analysis was revealed using powder X-ray diffraction (PXRD), Bruker D2 Phaser using LynxEye detector with radiation of a CuKα at a wavelength of 0.154 nm and Bruker Senterra laser Raman spectrometer fitted with frequency-doubled Nd-YAG laser with the wavelength of 532 nm. X-ray photoelectron spectroscopy (XPS; XSAM800, Kratos, Manchester, UK) was used to determine the oxidation state and elemental composition. The XPS used Al Kα (1487 eV) radiation as an excitation source, an average of 40 scans, time 1 min 17 s, 0.20 eV. Fourier transform infrared spectroscopy (FTIR, PerkinElmer Spectrum 100) was used to determine the sensing mechanism and characterize the materials by studying their functional groups. For sample preparation, solid samples of about 5 mg were mixed together with about 0.8 g of potassium bromide (KBr). The mixture was grinded using a pestle and mortar and the FTIR solid pellet was created using the pressed pellet technique.

Results and discussions

SEM was used to examine the surface morphologies of all the synthesized materials. The CNPs were spherical in structure and showed a

Fig. 4. SEM image of (a) CNPs, (b) $MnO₂$ NRs, (c) $MnO₂@ZIF-8$ and (d) $MnO₂@ZIF-8/CNPs$.

high degree of agglomeration, as shown in the SEM image in [Fig. 4](#page-3-0)a. The spheres were stacked on top of each other, forming nano-structured lumps. [Fig. 4](#page-3-0)b shows a representative SEM image of the hydrothermally synthesized $MnO₂$ nanorods (NRs), where $MnO₂$ is a onedimensional longitudinal rod. The surfaces of the $MnO₂$ rods were smooth and uniform, and the rods crossed each other without any uniform arrangement. The SEM image of the synthesized $MnO₂@ZIF-8$ is shown in [Fig. 4c](#page-3-0). The external roughness of $MnO_2@ZIF-8$ resulting from the attachment of MnO2 rods was covered by CNPs spheres (see [Fig. 4d](#page-3-0)). SEM-energy dispersive X-ray (EDX) was used to identify the elemental compositions of the CNPs, MnO_2 , $MnO_2@ZIF-8$, and $MnO_2@ZIF-8/CNPs$ composites (see the supporting document Fig. S2). The EDX profile revealed that the CNPs contained approximately 94.7 % carbon and 5.3 % oxygen.

The EDX profile of the $MnO₂$ sample has Mn 74.1 % and 25.9 % of oxygen. The EDX profile in Fig. S2c shows that $MnO₂@ZIF-8$ elemental composition was 45 % oxygen, 27.7 % Zn, 15.9 % Mn, and 12.0 % N. The MnO2@ZIF-8/CNPs sample contained C, Zn, Mn, O, and N; further confirmation was performed by XPS analysis.

The internal morphologies of $MnO₂$, CNPs, $MnO₂@ZIF-8$, and MnO2@ZIF-8/CNPs were studied using high-resolution transmission electron microscopy (HR-TEM). $MnO₂$ is a longitudinal rod with a

Fig. 5. HR-TEM image of (a-b) MnO₂ NRs, (c) MnO₂@ZIF-8, (d) CNPs, (e-f) MnO₂@ZIF-8/CNPs.

23–56 nm diameter, and the rods are randomly arranged (see [Fig. 5](#page-4-0)a). [Fig. 5](#page-4-0)b shows a $MnO₂$ lattice spacing of 0.311 nm, corresponding to the crystal plane (301). The crystal plane corresponds well with the XRD results (see Fig. 6b). The TEM image of MnO2@ZIF-8 (see [Fig. 5c](#page-4-0)) shows that ZIF-8 is a thin sheet with $MnO₂$ attached to it. The TEM image in [Fig. 5](#page-4-0)d reveals that the CNPs are chain-linked spheres that agglomerate. The particle size of the CNPs was in the range of 14–52 nm. The TEM image of the $MnO₂(@ZIF-8/CNPs$ composite reveals that the CNPs are randomly attached to the $MnO₂$ NRs, and some edges of the ZIF-8 sheetlike structure (see [Fig. 5](#page-4-0)e). [Fig. 5f](#page-4-0) shows the magnified area of the $MnO₂@ZIF-8/CNPs$ composite, wherein $MnO₂ NR$ surrounded the CNPs, and some CNPs were stacked on top of the rod.

Powder X-ray diffraction (PXRD) was done to study the structures of candle soot (CNPs), $MnO₂, MnO₂@ZIF-8, and MnO₂@ZIF-8/CNPs, as$ shown in Fig. 6. The XRD pattern of the CNPs shows two predominant peaks positioned at $2\theta = 24.5^\circ$ and 43.7°, which are attributed to the amorphous nature and graphitic structure of the CNPs [\[2\].](#page-12-0) The XRD pattern of the MnO₂ nanorods (Fig. 6b) shows peaks at $2\theta = 12.4^\circ, 18.1^\circ$, 28.8◦, 37.5◦, 41.6◦, 49.7◦, 56.2◦, 60.0◦, 65.2◦, 69.4◦, and 72.7◦ corresponding to the (110), (200), (310), (211), (301), (411), (600), (521), (002), (541), and (222) planes [JCPDS no. 044-0141], ascribed to tetragonal α-MnO₂ [\[26\].](#page-13-0) The presence of new XRD peaks added to MnO₂ in Fig. 6c shows 9.5° , 10.7° , 12.7° , and 16.1° , corresponding to the (011) , (002) , (112) , and (013) planes, respectively $[27]$, indicating the successful synthesis of ZIF-8 on MnO2 NRs. Two broad peaks of the CNPs were observed in the XRD pattern of $MnO₂@ZIF-8$, proving the successful preparation of MnO2@ZIF-8/CNPs through physical mixing (see Fig. 6d). Fig. 6(e-i) presents the FTIR spectra of the CNPs, 2-methylimidazole, MnO₂@ZIF-8, MnO₂, and MnO₂@ZIF-8/CNPs to study their chemical bonding nature. As shown in Fig. 6e, the FTIR spectra exhibited a broad peak at 3452 $\rm cm^{-1}$, representing O-H stretching. The 2864 and 2935 cm^{-1} peaks corresponded to C-H bonds from aldehydes and simple C-H bonds or carboxylic O-H bonds, respectively. The peak at 1636 cm⁻¹ represents C=C stretching, whereas the peak at 1384 cm⁻¹ corresponds to the CH3 group and O-H stretching. The bands at the lower end of the wavenumber region, including 663 cm⁻¹ and 1017 $\rm cm^{-1}$, correspond to $\rm sp^2$ and $\rm sp^3$ from the aromatics of amorphous CNPs [\[28\]](#page-13-0). The peaks at 683, 754, 1119, 1322, 1474, and 1606 cm⁻¹ were attributed to the aromatic ring of 2-methylimidazole (see Fig. 6f). The peaks detected at 531 cm^{-1} and 998 cm^{-1} of the MnO₂@ZIF-8 FTIR spectra confirm the bond between Zn and N. The peak observed at 672

 cm^{-1} is ascribed to O-Mn-O stretching, the peak at 1384 cm^{-1} is attributed to O-H stretching, and the broad peak at 3452 cm^{-1} is ascribed to the presence of absorbed H-O-H molecules, as shown in Fig. 6h [\[29\].](#page-13-0) Fig. 6i presents the FTIR spectrum with major peaks at 3452, 2935, 2864, 1636, 1384, 998, and 754 cm^{-1} , confirming the presence of $MnO₂$, CNPs, and ZIF-8 in the $MnO₂(@ZIF-8/CNPs)$ composite.

X-ray photoelectron spectroscopy (XPS) analysis revealed the elemental content, the oxidation state of the metals, and the oxygen species available on the sensing materials. The XPS full survey scan of the CNPs has confirmed the presence of carbon and oxygen atoms (see [Fig. 7a](#page-6-0)). The $MnO_2@ZIF-8$ and $MnO_2@ZIF-8/CNPs$ survey scans show Zn 2p, Mn 2p, N 1s, O1s, and C 1s peaks, indicating the elemental existence of zinc (Zn), manganese (Mn), nitrogen (N), oxygen (O), and carbon (C) (see [Fig. 7](#page-6-0)b and 7c). For the CNPs, the O 1s XPS spectrum shows only O_γ and O_β oxygen-reactive species (see [Table 1\)](#page-6-0), but the MnO2@ZIF-8 and MnO2@ZIF-8/CNPs have additional alpha oxygen (O_{α}). Generally, for metal oxides and semiconductor materials, O_{α} is ascribed to the lattice oxygen, O_6 represents the adsorbed oxygen species, and O_y is due to an adsorbed hydroxyl group (–OH) on the surface of the material (see [Fig. 7](#page-6-0)d-f) [\[30\]](#page-13-0). After the composites were formed by mixing the sensing materials, the total reactive oxygen species of the $MnO₂@ZIF-8/CNP, O_v$, and $O_β$ increased significantly. The presence of highly reactive oxygen species, particularly gamma oxygen (O_y) and beta oxygen (O_6) , on the surface of sensing materials, plays an important role in the sensing mechanism $[2,17]$. The Zn 2p XPS spectrum in [Fig. 8a](#page-7-0) displays two peaks at 1022.0 and 1045.4 eV which are attributed to Zn $2p_{3/2}$ and Zn $2p_{1/2}$, respectively. The difference in the binding energies of the two, which was 23.4 eV, indicated the existence of Zn^{2+} in $MnO₂@ZIF-8$. The Mn 2p XPS spectrum in [Fig. 8](#page-7-0)b presents two peaks at 642.0 and 653.6 eV, respectively, with a difference in the binding energy of 11.6 eV confirming the existence of Mn^{2+} in $MnO₂$ [\[31\]](#page-13-0). N 1s spectrum of $MnO_2@ZIF-8$ and $MnO_2@ZIF-8/CNPs$ in [Fig. 8](#page-7-0)c-d showed that there are three peaks positioned at 399.0, 400.0, and 406.6 eV which are assigned to N-C, N-Zn and N=C bonds, respectively $[32]$. The XPS peak assigned to the N-Zn bond confirms the successful synthesis of ZIF-8 by the successful coordination of zinc metal and nitrogen.

Sensing performances

The electrical characteristics of all the prepared sensors were

Fig. 7. XPS survey spectra of (a) CNPs (b) MnO2@ZIF-8, (c)MnO2@ZIF-8/CNPs, XPS 1 Os spectra of (d) CNPs, (e) MnO2@ZIF-8, (f) MnO2@ZIF-8/CNPs and (g) MnO₂.

evaluated at room temperature with an average relative humidity of approximately 40% during the detection of methanol, ethanol, acetone, 3-pentanone, and diethylamine vapor. The three sensing materials were used to fabricate the sensors; $MnO₂$, CNPs, and $MnO₂@ZIF-8$, which were prepared by either neat or combining the sensing materials and varying the masses of the composites, therefore sensor 1 (only CNPs),

Fig. 8. XPS spectra of (a) Zn 2p of MnO2@ZIF-8, (b) Mn 2p of MnO2@ZIF-8, (c) N 1s of MnO2@ZIF-8, and (d) N 1s of MnO2@ZIF-8/CNPs.

sensor 2 (only MnO₂), sensor 3 (only MnO₂@ZIF-8), sensor 4 $(MnO₂@ZIF-8/CNPs$ with a mass ratio of 1:1), sensor 5 $(MnO₂@ZIF-8$ / CNPs with mass ratio with a mass ratio of 2:1), and sensor 6 ($MnO₂(Q -)$ ZIF-8/CNPs with a mass ratio of 3:1). The relative change in resistance (ΔR) was recorded for all fabricated sensors during testing the performance of the sensors.

Among the prepared sensors, the $MnO₂$ NRs sensor did not show any meaningful change in the sensor response during exposure to analyte vapors at low concentrations; however, at high concentrations, the sensor responded (See Fig. S3). All the remaining sensors responded well to the targeted analyte during the exposure and recovered extremely well to their baseline after removing the analyte vapor from the chamber, which is a good indication of the sensors' self-regeneration ability. As indicated earlier, plain $MnO₂$ NRs as an active sensing material were not responsive; however, when ZIF-8 was incorporated with MnO2 using a one-pot synthesis method to synthesize $MnO₂@ZIF-8$ as an active sensing material, and the sensor exhibited a response. This improvement was due to the synergistic effect of the two sensing materials, which increased the percentages of O_γ and O_β after MnO₂@ZIF-8 formed (See [Table 1](#page-6-0)).

Using CNPs as a sensing material has advantages over other sensing materials, such as fast recovery, good stability, lower signal-to-ratio, and the ability to improve the sensitivity of the sensors [\[17\]](#page-13-0). Possession of such excellent properties would increase the performance of the sensors. For the detection of diethylamine vapor, we used variable mass ratios of MnO2@ZIF-8 to CNPs in the composites; for example, sensor 4 $(MnO₂@ZIF-8/CNPs$ with a mass ratio of 1:1), sensor 5 $(MnO₂@ZIF-8/$ CNPs with mass ratio with a mass ratio of 2:1), and sensor 6 ($MnO₂(Q-$ ZIF-8/CNPs with a mass ratio of 3:1). It can be seen from [Fig. 9](#page-8-0) that at the first injection, at a concentration of 11.82 ppm, there was a noticeable increase in the relative responses from approximately 0.75, 8.3, and 150 Ω . This shows that the amount of MnO₂@ZIF-8 within the composite sensors plays a crucial role in improving the sensing response. The sign of the responses has changed as we increase the amount of $MnO₂$ in the composites. At a 1:1 mass ratio, the sensor behaved as a ptype with the reducing gas diethylamine vapor, although, $MnO₂$ is an ntype semiconductor. However, as the amount of $MnO₂$ increases, the behaviour changes to n-type and the conductivity of the sensors increases as the concentration of the analyte increases. The reduced

electron-depletion layer thickness and potential barrier increase the sensor's conductivity.

The sensor with a higher $MnO_2@ZIF-8$ content had a relatively fast response-recovery time, and the sensor with a lower $MnO₂@ZIF-8$ content was slow to respond and recover [\(Table 2](#page-8-0) and [Fig. 10\)](#page-9-0). The response and recovery times of the sensors are reported based on the time required to achieve 90% response and recovery.

Sensitivity, selectivity, and repeatability. The sensitivity of the gas sensors during the detection of vapor analytes was taken from the gradient of the calibration curves for relative resistance (ΔR) vs concentration (C) and it was determined using the formula $S=\frac{\Delta R}{\Delta C}$ [\[17\].](#page-13-0) The calculated sensitivities of the analyte vapors to their respective sensors are summarized in Table S1. It was observed that the sensitivities of the materials, namely, CNPs, $MnO₂$ NRs, and $MnO₂$ -CNPs were extremely low for all the tested vapor analytes, whereas $MnO₂@ZIF-8$ and the MnO2@ZIF-8/CNPs composites showed better sensitivity. The sensitivity of the $MnO₂@ZIF-8/CNPs$ composites increased with an increase in the MnO2@ZIF-8 content within the composite [\(Fig. 11](#page-9-0)a). Sensor 6 was highly sensitive to diethylamine vapor, with a sensitivity of 5.49 Ω ppm⁻¹ and very poor sensitivity to ethanol vapor (0.0001 Ω ppm⁻¹). Thus, among all the sensors prepared and tested for all the selected vapors, sensor 6 was the best for the detection of diethylamine vapor with high sensitivity.

Selectivity is one of the most important parameters in sensor functionality. The sensor can detect the target analyte from interference vapors and only shows the sensing response of the targeted vapor analyte. Therefore, sensor 6 was selected as the best sensor for the selectivity test. The targeted analytes were methanol, ethanol, acetone, 3 pentanone, and diethylamine mixed vapors response and the individual analyte vapor responses were compared (see [Fig. 11b](#page-9-0)). The analytes were prepared by mixing 1 mL of each analyte (methanol, ethanol, acetone, 3-pentanone, and dimethylamine vapors) to obtain 5 mL of the analyte mixture. Then from the 5 mL of the mixed analyte, 5 μL was injected into a 20 L round bottom flask (chamber), and sensor 6 was exposed to mixed analyte vapor. The sensor response was 176 Ω for the mixed analytes, and the pure diethylamine analyte vapor response was 151 Ω ([Fig. 11](#page-9-0)b). The mixed analyte response is only 14% of that of pure diethylamine; this increment is due to interference mainly from acetone, which is the second most sensitive analyte. Nevertheless, the sensor

Fig. 9. Dynamic response as a function of time at different concentrations of diethylamine vapor on (a and b) sensors 4, (c and d) sensor 5, and (e and f) sensor 6 and their respective response calibration curves.

Table 2

Response and recovery times of the sensors during the detection of diethylamine vapor.

Sensors	Response time (s)	Response time (s)
Sensor 4	164	191
Sensor 5	87	45
Sensor ₆	67	22

response for the mixed analyte is close to the pure diethylamine vapor. Therefore, it is possible to say that our sensor can selectively detect the targeted analyte.

The repeatability of gas sensors is another critical parameter because it shows the stability of the sensors after several exposures to the analyte vapor, in which the sensor can reproduce the same reading for the same concentration under the same conditions over time [\[33,34\].](#page-13-0) In real applications, there is a need for a sensor that reproduces the same reading over time. Thus, sensors 5 and 6 reusability studies were performed to detect diethylamine vapor by injecting 47.27 ppm of diethylamine vapor for five consecutive cycles for each sensor. The maximum response was found to be approximately 33.95 \pm 0.40 Ω and 329.19 \pm 9.26 Ω respectively (see [Fig. 11](#page-9-0)c-d). The sensor responses were approximately

90% the same in magnitude, and the sensors returned to their baseline after gas removal, showing the sensors' good stability and reusability.

Humidity

Exposing a gas sensor to different relative humidity conditions is an important factor to investigate because, in many cases, most sensors exhibit a constant change in relative humidity during real-time applications [\[35,36\].](#page-13-0) Changes in atmospheric relative humidity can result in more than a 50% change in the sensor's performance [\[37\].](#page-13-0) Thus, a sensor that provides slight changes at different relative humidities is still considered good. However, the main aim was to obtain a sensor that was unaffected by humidity conditions. Hence, our best-performing sensor, 6, was investigated in the relative humidity (RH) range of 39% to 60% during the detection of diethylamine vapor. Specifically, 11.82 ppm of diethylamine vapor was used and detected for three trials at relative humidities of 44%, 55%, and 64%, and the maximum response was found to be 154, 161, and 183 Ω , respectively (see [Fig. 12](#page-9-0)a). An increase in relative humidity from 44 to 64 % results in a slight increase in gas response, which could result from water molecules trapped on the surface of the gas sensor. The sensor maintained the same shape but was tested under different humidity conditions. However, the response of the

Fig. 10. Response recovery times of sensors 5 (a) and 6 (b) during the detection of diethylamine vapor.

Fig. 11. (a) Comparative sensitivity of analytes on sensors, (b) comparative vapor response of the mixture vapor and individual analytes, (c) repeatability graph of sensor 5, and (d) sensor 6 on diethylamine.

Fig. 12. (a) Humidity investigation of sensor 6 and (b) response-recovery time under different humidity conditions.

sensor significantly changed at greater than 85% RH (the result is not shown here). Interestingly, with an increase in humidity conditions from 44 to 64 % RH, the response time during the detection of diethylamine vapor increased from 72 s to 90 s, and the recovery time changed from 25 s to 38 s (see Fig. 12b).

Limit of detection

The limit of detection (LOD) in gas sensors is the minimum possible vapor concentration a gas sensor can detect. The LOD of sensor 6 for the detection of diethylamine vapor was quantified. The relationship between concentrations from 11.82 ppm to 59.09 ppm and electrical response under the resistance parameter was linear with a gradient of 5.49 $Ω$ *ppm*^{-1} and the correlation coefficient (*R*) is 0.98 (see [Fig. 9f](#page-8-0)). The formula used to calculate the detection limit is as follows: LOD = 3 \times RMS/slope [\[38\]](#page-13-0), where the RMS is the standard deviation with a value of 0.001. From the calculations, the LOD of sensor 6 for detecting diethylamine vapor is 5.5 ppb. Sensor 6 could detect diethylamine vapors at extremely low concentrations (ppb level).

Sensing mechanism

Different sensing materials show different sensing mechanisms; various polymers have different sensing mechanisms. However, the most dominant sensing mechanisms are electrostatic between the interaction of electron reach polymer, for example, nitrogen-containing backbone and electron-deficient analyte molecules, polarization, Lewis acid and base interactions between the analyte molecules and the polymer [\[39,40\]](#page-13-0). On the other hand, the interaction between the adsorbed analyte molecules leads to the swelling of the polymer, thus increasing the overall volume and pushing away the polymer chains from one another; this causes a change in the sensors' conductivity [\[41\]](#page-13-0). In the case of carbonaceous materials, the dominant accepted sensing mechanism is charge transfer between carbonaceous nanomaterials and molecules adsorbed on their surface $[42]$. In a recent report, the presence of reactive oxygen species on the carbonaceous materials, the Oγ, and Oβ, do have similar sensing mechanisms as SMO [\[14,16,17\]](#page-13-0). The generally accepted sensing mechanism for SMO is once the organic analyte molecules are adsorbed on the surface of the SMO, the reactive oxygen on the SMO's surface reacts and converts the analyte molecules into $CO₂$ and $H₂O$.

Based on the gas response behavior of the $MnO₂@ZIF-8/CNPs$ (on sensor 6), the composite exhibits the characteristics of a p-type semiconductor during the detection of vapor analytes. Incorporating CNPs into MnO2@ZIF-8 forms a p-n heterojunction because CNPs behave like p-type semiconductors. Therefore, the excellent performance of the $MnO₂@ZIF-8/CNPs$ is due to the p-n heterojunction formed at the interfaces. The advantage of heterojunction formation is that electrons can easily transfer from the MnO₂@ZIF-8 into the CNPs to form enough oxygen vacancies on the surface of $MnO₂(@ZIF-8. The p-n heterojunction$ also helps to increase the electronically charged oxygen vacancies, leading to an increase in the conductivity of the composite. The formation of heterojunctions also helps adsorb more oxygen molecules to form extra active sites, eventually capturing electrons from $MnO₂(QZIF-$ 8. During the sensor's exposure to the analyte, the oxygen ions react with the target gas molecules [\[43\]](#page-13-0) (See [Table 1\)](#page-6-0).

It is worth mentioning that when a heterojunction is formed, the sensors' semiconductor behavior depends on the sensing materials' dominant behavior, either p- or n-type semiconductors. For example, sensor 4 (MnO₂@ZIF-8/CNPs with a mass ratio of 1:1) is dominated by the CNPs semiconductor character, n-type (see [Fig. 12](#page-9-0)), with similar behavior to the CNPs sensor. When the mass of $MnO₂@ZIF-8$ was increased, the CNPs were kept constant (see sensors 5 and 6), and the gas-sensing behavior changed from n-type to p-type semiconductor behavior. This is due to the dominant material $(MnO₂@ZIF-8)$, the ptype (see [Fig. 12](#page-9-0)).

On the surface of the sensing materials, the adsorbed oxygen molecules react with the sensing materials to form a depletion layer and turn oxygen molecules into highly reactive species (O_2^2 , O_2^2 , and O) [\[44](#page-13-0)–46]. Generally, most carriers in n-type semiconductor metal oxides are electrons. Thus, electrons are extracted from such materials when exposed to an oxidizing gas, leading to increased resistance. In p-type

semiconductor metal oxides, however, holes are the majority carriers during sensing [\[47\]](#page-13-0). In p-type sensing materials, the adsorbed oxygen molecules form a hole accumulation layer. The holes are extracted from the p-type semiconductor metal oxide when exposed to an oxidizing gas (acceptor), decreasing resistance.

For the diethylamine molecule, ethyl $(-CH₂CH₃)$ is an electrondonating group and the electron cloud density on the nitrogen atom increases during the interaction of the analyte and the sensing material [\[48\]](#page-13-0). The resistance increases with the vapor concentration when the diethylamine molecules interact with the CNPs sensor and sensor 4. However, when sensors 5 and 6 were exposed to analyte vapor, the sensors' resistance decreased as the diethylamine concentration increased. Although the $MnO₂@ZIF-8$ -based sensor response was relatively small in magnitude during exposure to vapor, introducing the CNPs in the composites significantly improved the sensor response. This is due to the presence of oxygen molecules in the carbon soot (CNPs) (see [Table 1\)](#page-6-0), which are converted into reactive oxygen species during sensing [\[49\].](#page-13-0) The EDX results confirmed that the CNPs contained approximately 5.3% oxygen. The XPS analysis (see [Fig. 7](#page-6-0)) also confirmed the oxygen species formed during the pyrolysis reaction in the presence of atmospheric oxygen.

The *In-situ* FTIR coupled with an LCR meter method was used for sensors based on CNPs, $MnO_2@ZIF-8/CNPs$ (1:1 mass ratio), $MnO_2@-$ ZIF-8/CNPs (2:1 mass ratio), and $MnO₂@ZIF-8/CNPs$ (3:1 mass ratio) to study the sensing mechanism of gaseous diethylamine. During the *in-situ* FTIR coupled with the LCR meter connected to a chosen sensor measurement, the relative sensing response was recorded simultaneously the FTIR spectra were taken every two minutes. The intensity of $CO₂$ IR bands at 668 cm^{-1} and 2349 to 2277 cm^{-1} , the bending and asymmetric stretching mode, respectively [\[50,51\]](#page-13-0), were used to monitor the surface reaction. The intensity of the $CO₂$ IR bands continued to grow as the diethylamine vapor exposure of the sensor increased, as shown in [Figs. 13 and 14.](#page-11-0) It is observed that the $CO₂$ bending shows a single peak, indicating pure $CO₂$, while $CO₂$ asymmetric shows doublet peaks, which could be a mixture of CO_2 , H₂O, and/or carbon monoxide [\[52\]](#page-13-0). The CO_2 formation is due to the deep oxidation of diethylamine vapor on the surface of the sensing materials, and $CO₂$ molecules diffuse from the sensing material. At $t = 2$ min, the $CO₂$ band intensities were very weak for all the sensors, but as the exposure time increased, the $CO₂$ bands became intense.

We observed that the intensity of the $CO₂$ band increased when the sensing materials formed heterojunctions; for example, the intensity of the $CO₂$ IR band in the case of CNPs increased when $MnO₂(@ZIF-8 / CNPs)$ were formed. This could be related to the increased reactive oxygen species on the surface of the sensing materials when the composite was formed ([Table 1](#page-6-0)). Furthermore, the amount of $MnO₂@ZIF-8$ in the composites affects the intensity of the $CO₂$ band (see the inset of [Fig. 13a](#page-11-0)–d). All sensors underwent deep oxidation of the dimethylamine vapor to carbon dioxide and other small molecules, such as $H₂O$ and NO2; even the pure carbon soot sensor showed the same decomposition mechanism, the analyte into $CO₂$ (See [Fig. 13](#page-11-0)a inset). To understand the relationship between the sensitivity, surface reaction rate, and $CO₂$ band intensities, we employ the area under the $CO₂$ curve at 668 cm⁻¹ using Gaussian curves from 2 to 12 min of exposure. The plotted curve of the areas under the curve of the CO₂ bends at 668 cm⁻¹ against time ([Fig. 14](#page-12-0)), and their slopes were compared to the sensitivity. The gradient can be assumed as the reaction rate on the sensing material. Therefore, the sensor's sensitivity is directly proportional to the reaction rate on the surface of the sensing material, as summarized in [Table 3.](#page-12-0) For example, the best-performing sensor, the 3:1 mass ratio of $MnO_2@ZIF-8/CNPs$, recorded the highest value of 0.0776 of the area under the curve with respect to time. This indicates a parameter that can be used to measure the sensor performance directly related to the sensor's sensitivity.

Conclusion

In summary, MnO₂ NRs, carbon soot, MnO₂@ZIF-8, and MnO₂@ZIF-8/CNPs were successfully prepared and fully characterized using SEM, HR-TEM, FTIR, PXRD, and XPS. The prepared materials were used to fabricate solid-state gas sensors, and $MnO_2@ZIF-8/CNPs$ with a mass ratio of 3:1 (named sensor 6) was highly sensitive and selective for detecting diethylamine vapor over acetone, methanol, ethanol, and 3 pentanone vapors. Sensor 6 recorded 5.5 ppb as the detection limit, and our sensor showed fast response-recovery times of 67 s and 22 s. The fabricated sensor was also minimally affected by changes in humidity. The *in situ* FTIR coupled with an LCR meter method was used to study the sensing mechanism of sensor 6 interacting with diethylamine vapor.

The sensor mechanism was by decomposition of the analyte vapor on the surface of the sensing material to $CO₂$ and other molecules. This was confirmed by monitoring the intensity of the $CO₂$ bands at around 2350 and 668 cm⁻¹. The CO₂ IR band intensity at 668 cm⁻¹ as the contact time between the sensor and analyte progresses. Furthermore, the sensor's sensitivity is directly proportional to the sensing materials' surface reaction rate.
